Disclaimer

This document aims to combine a review of the best available evidence for acute pain management with current clinical and expert practice, rather than to formulate specific clinical practice recommendations. It is designed to provide information based on the best evidence available at the time of publication to assist in decision-making. The information provided is not intended to over-ride the clinical expertise of health care professionals and its use is subject to the clinician's judgement and the patient's preference in each individual case. There is no substitute for the skilled assessment of each individual patient's health status, circumstances and perspectives, which health care practitioners will then use to select the treatments that are relevant and appropriate to that person.

This document can be downloaded from the ANZCA website: http://www.anzca.edu.au/resources/college-publications. Copies of the document can be ordered through the Australian and New Zealand College of Anaesthetists on +61 3 9510 6299.

Foreword

The imperative to treat acute pain with innovative evidence-based, patient-centred strategies has never been greater. The lofty goal of personalised, harm-free and adequate relief for every person experiencing acute pain remains just that. The fact that it is not yet reality is more of a testimony to the enormity and complexity of the task rather than for want of trying as can be seen by the exponential increase in publications on this topic.

In 2007, Dr Frank Brennan, Prof Daniel Carr and Prof Michael Cousins, chair of the committee that developed the first edition of *Acute Pain Management: Scientific Evidence,* highlighted the moral imperative to treat pain (Brennan 2007). Indeed, they stated that there is an obligation to treat pain on the basis of restoring patient autonomy and an ethical duty to relieve suffering. This was followed by the "Declaration of Montreal", the outcome of the first International Pain Summit in 2010, which called for "*access to pain management as a fundamental human right*" (Cousins 2011).

The moral imperative to treat all forms of pain remains. Not only does unrelieved pain impair an individual's ability to exercise their fundamental autonomy, it can lead to a wide range of harms even in the short term (Brennan 2007). The well-intentioned promotion that occurred at the turn of this century of the greater use of opioids, in pursuit of the elusive goal of effective pain management for all, has, with the benefit of hindsight, resulted in unexpected injury for many. The number of unintentional drug-induced deaths in Australia continues to rise; prescription opioids and benzodiazepines being the main culprits (Penington Institute 2019). Although many unwanted side-effects are the consequence of long-term use, many opioids are started in the acute pain setting, particularly postoperatively, setting patients on the path to long term use (Bergomi 2018, Brummett 2017, Roughead 2019). Indeed, the use of opioids in acute pain is not without other risks either including opioid-induced ventilatory impairment, cognitive impairment, falls and gastrointestinal adverse effects (Macintyre 2011).

The pendulum seems to be swinging back to a more opioid-phobic position which is unlikely to deliver high-quality care for many individuals either (Kharasch 2020. The pressing need is to better understand what does and does not work from what is already known so that better choices can be made for individuals. The publication of the fifth edition of *Acute Pain Management: Scientific Evidence* is therefore very timely. Recognising the limitations of opioids in the management of acute pain has driven a surge in interest of alternative pain management techniques such as novel non-opioid drugs, new options for regional blockade and non-pharmacological techniques over the last decade (Albrecht 2020, Guay 2017).

For a small percentage of patients however acute pain is still not adequately managed despite the burgeoning range of multimodal pain management techniques, leaving patients at risk of transition to chronicity. Many of the risk factors lie in the psychological, social, cultural and spiritual realms (Sobol-Kwapinska 2016). The need for a broader sociopsychobiomedical approach has been recognised as evidenced by the development of new approaches to preoperative preparation for surgery and extended postoperative care. Transitional pain services and Acute Pain Service outpatient clinics are now being employed to specifically support patients to safely taper medications and identify those who may need early referral to chronic pain services (Huang 2016). Pleasingly, there is now an emerging evidence base addressing the effectiveness of such services from a range of perspectives (Gray 2017). At a time when health system budgets are under huge scrutiny as the costs of new drugs and technologies escalate at unsustainable rates, pain services and even individual pain management techniques are under more pressure than ever to demonstrate cost

benefit especially from reducing complications and facilitating early discharge from hospital (Schofield 2019).

Acute Pain Management: Scientific Evidence: 5th Edition is larger than ever yet comfortingly familiar. In this fifth edition, Professor Schug and the editorial team have compiled the latest high-quality offering of this internationally renowned publication from the Australian and New Zealand College of Anaesthetists and its Faculty of Pain Medicine. It brings together the most recent evidence in acute pain management from the last five years, properly evaluated and collated in the one resource. Its structure has evolved from the solid foundations established in the previous editions, commencing with the first edition published in 1999 by the National Health and Medical Research Council (NHMRC). The foresight of Professor Michael Cousins and the first multidisciplinary committee to develop this first text based on the NHMRC designation of levels of evidence was visionary. Professor Pamela Macintyre and the editorial teams of the subsequent editions in 2005 and 2010 meticulously built on this. In 2015 Professor Stefan Schug and the editorial team enhanced the fourth edition by adding quality scoring using the Jadad Score to the assessment of the evidence. This enabled conflicting evidence to be addressed and enhanced the production of the Key Messages. The fifth edition retains this now standard structure.

Once again, the medical community is indebted to Professor Schug and the editorial team for their diligence and dedication over the last two years. The production of the fifth edition has been an enormous task as the evidence base has more than doubled in some domains and grown even more in others with the addition of some new topic areas to assess. Most sections have more than doubled or trebled in size and, indeed, a second volume has been required for acute pain management in children to contain the growing evidence base in this domain that has tripled. The benefit of the five-yearly cycle of literature review over time is the consolidation of Key Messages with the strengthening of many and only a few being reversed. Many new Key Messages have also been added. Users of this text can feel confident that the information has been expertly assessed and can be relied on to inform their clinical practice which was exactly the original aim of the first edition.

In this edition of *Acute Pain Management: Scientific Evidence,* the chapters on predisposing factors, psychological contributors, hypnosis and alternative strategies to medications contain much new information, reflecting the increasing interest in a "whole-person" approach in addition to more traditional techniques. However, the latter remain of interest as shown by sections on new routes of administration, novel opioids and new uses for old drugs. Cannabis products are just the latest to be addressed. Contemporary cannabis research has been mostly focused on the chronic pain setting where the evidence to date suggests significant limitations in effectiveness and efficacy (Beaulieu 2016, Stockings 2018). However, newer research is addressing a range of acute pain settings with particular interest in the potential for opioid sparing and tapering (Khan 2019).

The use of ultrasound scanning to guide neuraxial and peripheral regional blockade, especially catheter techniques, has become the accepted norm and is being used to explore an increasing number of regional anaesthesia techniques (Anim-Somuah 2018, Smith 2020).

Optimal pain management for every person experiencing acute pain remains elusive; however, the evidence base continues to grow taking us step by step closer to the lofty goal of personalised pain management. The imperative to manage acute pain remains with the caveats that it must be safe and best be personalised. *Acute Pain Management: Scientific Evidence: 5th Edition* provides the latest evidence to support decision-making with that goal in mind for everyone experiencing acute pain.

Introduction

This is the fifth edition of the book A*cute Pain Management: Scientific Evidence*. The first edition was written by a multidisciplinary committee headed by Professor Michael Cousins and published by the National Health and Medical Research Council (NHMRC) in 1999.

The second and third editions were written by multiple contributors and a working group chaired by Professor Pam Macintyre. The editions were approved by the NHMRC and published by the Australian and New Zealand College of Anaesthetists (ANZCA) and its Faculty of Pain Medicine (FPM) in 2005 and 2010. They were also endorsed by other major organisations worldwide.

As guidelines and key sources of information should be revised as further evidence accumulates (ideally every 5 years), a fourth edition was written by multiple contributors and an editorial working group chaired by Professor Stephan Schug and published by ANZCA and its FPM in 2015. In view of the NHMRC changing its criteria, this edition was not submitted for NHMRC approval, but it was widely endorsed by many significant national and international organisations - the International Association for the Study of Pain (IASP), the Royal College of Anaesthetists and its Faculty of Pain Medicine, the American Academy of Pain Medicine, the Australian Pain Society, Australasian College of Sport and Exercise Physicians, the Australasian Faculty of Rehabilitation Medicine, the College of Anaesthesiologists of the Academies of Medicine of Malaysia and Singapore, the College of Intensive Care Medicine of Australia and New Zealand, the European Society of Regional Anaesthesia and Pain Therapy (ESRA), the Faculty of Pain Medicine of the College of Anaesthetists of Ireland, the Hong Kong College of Anaesthesiologists, the Hong Kong Pain Society, the Malaysian Association for the Study of Pain, the New Zealand Pain Society, the Pain Association of Singapore, PainSA (South Africa), PROSPECT (Procedure Specific Postoperative Pain Management), the Royal Australasian College of Physicians, the Royal Australian and New Zealand College of Psychiatrists, the Royal Australasian College of Surgeons and the South African Society of Anaesthesiologists.

With 5 years' further growth in evidence, it was seen as timely to reassess the available evidence, aiming for a release of the new document in 2020. ANZCA and the FPM therefore again took responsibility for revising and updating this reference to its fifth edition. As for the fourth edition, endorsement is currently being sought from a number of key organisations.

An editorial working group was convened to coordinate and oversee the development process, to edit the reference and also contribute updates to some sections – members were Prof Stephan Schug, A/Prof Greta Palmer, Prof David Scott, Dr Mark Alcock, Dr Richard Halliwell, and Dr Jeff Mott. While all members of the working group contributed to the whole document, A/Prof Greta Palmer and Dr Mark Alcock provided specific input and expertise to the paediatric section. This section will remain as Chapter 10 in the PDF of the book, but In view of the largely increased amount of information in the paediatric section, it will be published as a separate volume II of the hardcopy of the book.

The working group was also assisted by an editorial advisory group comprising Dr Mark Rockett, nominated by the Faculty of Pain Medicine, Royal College of Anaesthetists in the United Kingdom, and Dr Clara Sze Ming Wong, nominated by the Hong Kong College of Anaesthesiologists.

A large panel of contributors was enlisted to draft sections of the document and a multidisciplinary consultative committee was chosen to review the draft of the document and contribute more broadly as required. To ensure general applicability and inclusiveness, there was a very wide range of experts on the contributor and multidisciplinary committees, including medical, nursing, allied health and complementary medicine professionals and consumers.

Acute Pain Management: Scientific Evidence: 5th Edition covers a wide range of clinical areas. The aim of the document is, as with the first four editions, to combine a review of the best available evidence for acute pain management with current clinical and expert practice, rather than to formulate specific clinical practice guidelines. Accordingly, the document aims to summarise the substantial amount of evidence currently available for the management of acute pain in a concise, accessible, and easily readable form to assist the practising health professional. New and updated content has been incorporated with that of the previous version of the book.

A detailed description of the methodology used to generate this document can be found in Appendix B. The following summarises the most important information on the methodology.

Review of the evidence

This document is a revision of the previous edition of *Acute Pain Management: Scientific Evidence* published in 2015. Therefore most of the new evidence included in this fifth edition has been published from August 2014 onwards, which was the cut-off date for literature inclusion in the fourth edition. Literature was considered when published between this date and the cut-off date for this fifth edition (August 2019). However, in rare circumstances, references published after this cut-off were considered but only if they were of high relevance and encountered in the editorial process. In addition, high-quality evidence-based guidelines have been published independently by a number of organisations in the areas of acute back and musculoskeletal pain and the chapters relevant to the management of these conditions refer to these guidelines.

Levels of evidence

Levels of evidence continue to be documented according to the NHMRC designation (NHMRC 1999 **GL**).

Levels of evidence	
I	Evidence obtained from a systematic review of all relevant randomised controlled trials (RCTs)
II	Evidence obtained from at least one properly designed randomised controlled trial
III-1	Evidence obtained from well-designed pseudo-randomised controlled trials (alternate allocation or some other method)
III-2	Evidence obtained from comparative studies with concurrent controls and allocation not randomised (cohort studies), case-controlled studies or interrupted time series with a control group
III-3	Evidence obtained from comparative studies with historical control, two or more single-arm studies, or interrupted time series without a parallel control group
IV	Evidence obtained from case series, either post test or pretest and post-test
Clinical practice points	
☑	Recommended best practice based on clinical experience and expert opinion

Quality scoring

As for the fourth edition, evidence was subjected to quality scoring and other types of references identified to enhance the value of the information provided.

Systematic reviews and meta-analyses

- Reviews performed by the Cochrane Collaboration are identified as [Cochrane] in the text eg (Derry 2013 **Level I** [Cochrane]);
- Reviews that overtly state that the review conformed with an evidence-based minimum set of items for reporting referred to as Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) (Liberati 2009 **GL**) are identified as [PRISMA] eg (Moore 2014 **Level I** [PRISMA]);
- Reviews that overtly state that the review conformed with standards previously published as Quality of Reporting of Meta-analyses (QUOROM) (Moher 1999 **GL**), a precursor of PRISMA, are identified as [QUOROM] eg (Macedo 2006 **Level I** [QUOROM]);
- Non-Cochrane meta-analyses (of RCTs) that did not provide evidence of using PRISMA or QUOROM quality and reporting methods are only labelled Level I eg (Thorlund 2014 **Level I**);
- Systematic reviews that included studies other than RCTs are assigned the level of evidence of their lowest level component studies (as outlined in the NHMRC designation of evidence levels [NHMRC 1999 **GL**]) and identified by SR following the level of evidence eg (von Plato 2018 **Level IV SR** [PRISMA], 9 RCTs & 10 studies, n=949);
- Network meta-analyses are identified as [NMA] eg (Martinez 2017 **Level I** (NMA), 135 RCTs, n=13,287).

For all systematic reviews and meta-analyses, the number of RCTs for Level I and the number of studies for all other levels is reported as well as the number of subjects included in these, if reported or immediately obvious eg (Rabbie 2013 **Level I** [Cochrane], 9 RCTs, n=4,473); if this is not the case, the term unspecified is used eg (Hughes 2011 **Level IV SR**, 5 studies, n unspecified).

Randomised-controlled trials

The Jadad scoring instrument was used to score the quality of all RCTs (Level II) (Jadad 1996). The Jadad Score (JS) ranges from 0 (lowest quality) to 5 (highest quality) and is based on randomisation and blinding methods used and accurate accounting of study participants.

In addition to the Jadad score, the number of patients randomised (prior to dropouts) is reported for all Level II references eg (Chan 2010 **Level II**, n=4,484, JS 5).

Other evidence

No quality evaluation was undertaken for lower ranked evidence (Level III and Level IV), when this was the highest available level of evidence. However, the number of patients or events included is provided if reported in the publication and the size of the study relates to the quality of the evidence eg (Morton 2010 **Level IV**, n=5,065).

Identification of other types of references

Narrative reviews containing such evidence are identified by NR following the reference eg (Graham 2013 **NR**). Other study types have been included where relevant and identified by a research identifier following the reference. Thus, readers will find CR (for case report) eg (Madadi 2010 **CR**), GL for clinical practice guidelines eg (Kowalski 2011 **GL**), BS if presenting basic science or animal data eg (LaCrois-Fralish 2011 **BS**), PK if presenting pharmacokinetic study eg (Holford 2012 **PK**) and EH if presenting human experimental data eg (Saxena 2013 **EH**). The latter two were also assigned an evidence level in line with NHMRC hierarchy if applicable eg (Williams 2002 **Level II PK**, n=96, JS 4).

Conflicting evidence

If evidence was consistent, the most recent, highest hierarchy and highest quality references were used. If evidence was conflicting, the same approach was taken (identifying highest level, highest quality evidence); however, examples were given of differences within the literature so that readers could appreciate the ongoing debate. In some instances, particularly in acute pain management in various patient populations, evidence was limited to case reports only, which is made clear in the document as the best available evidence in this instance.

Key messages

Key messages for each topic are given ranked by the highest level of evidence available to support them, or with a tick box symbol indicating that they are based on clinical experience or expert opinion. Levels of evidence were documented according to the NHMRC designation and, as for the previous four editions of this document, clinical practice points have been added.

Key messages are presented in order of level of evidence from the highest to the lowest. Key messages referring to information extracted from Cochrane meta-analyses were marked "Level I [Cochrane Review]", and these were listed first, followed by those marked "Level I [PRISMA]", "Level I [QUOROM]" and "Level I". Level II evidence was included in key messages if supported by a single sufficiently large, or at least two smaller, high quality Level II studies as determined by the editors. Key messages based on lower levels of evidence than Level II are presented with those based upon systematic reviews listed before those based on studies at each level of evidence.

There is no standard approach to updating wording or strength of evidence of existing guideline recommendations (Vernooij 2014 **GL**). An indication of how the key messages in this fifth edition relate to those in the preceding fourth edition is provided. An adapted version of the system used by Johnston et al (Johnston 2003) to reflect the implications of new evidence on clinical recommendations was therefore used as previously. Where the new evidence led to reversal of a conclusion and key message, this was noted in the text.

Review and revision of key messages	
New	New evidence leads to new key message(s).
Unchanged	The new evidence is consistent with the data used to formulate the original key message. The key message in the original report remains unchanged.
Strengthened	The new evidence is consistent with the data used to formulate the original key message. The key message in the original report remains unchanged or expanded. The level of evidence and/or content of the key message in the original report has been strengthened to reflect this additional evidence.
Weakened	The new evidence is inconsistent with the data used to inform the original key message(s). However, the new evidence does not alter the key message but weakens the level of evidence.
Qualified	The new evidence is consistent with the data used to formulate the original key message. The key message in the original report remains unchanged but applicability may be limited to specific patient groups/ circumstances.
Reversed	The new evidence is inconsistent with the data used to inform the original key message(s). The strength of the new evidence alters the conclusions of the original document.

Note *Clinical and scientific judgement informed the choices made by the editorial working group members; there was no mandatory threshold of new evidence (eg number of studies, types of studies, magnitude of statistical findings) that had to be met before classification into categories occurred.*

The first letter of each of the words (New, Unchanged etc) was used to denote the changes (if any) from the last edition of this document.

Acknowledgements

The production of a document such as this requires a considerable amount of time over a long period and the generous input of many. All contributions were honorary and the time contributed freely by the members of the editorial working group and the many contributors need to be acknowledged in particular. The institutional support in terms of time and resources from many hospital departments, including Departments of Anaesthesia throughout Australia and New Zealand, is difficult to quantify but is gratefully acknowledged; these include Queensland Children's Hospital, Redcliffe Hospital, St Vincent's Hospital Melbourne and Westmead Hospital.

A/Prof Greta Palmer would like to specifically thank both the Royal Children's and Royal Melbourne Hospitals for protected non-clinical time to dedicate to the editing task and the University of Melbourne for access to its expansive online journal subscriptions.

Special thanks are also extended to the staff at ANZCA and the FPM, in particular Ms Liane Reynolds and Ms Frances Rowsell for their ongoing input to the process. The ANZCA library was an extremely effective and valuable resource once more, in particular for provision of difficult to access references.

Stephan Schug
On behalf of the Editorial Working Group of the Australian New Zealand College of Anaesthetists and its Faculty of Pain Medicine

List of tables

List of figures

Summary of key messages

A description of the levels of evidence and associated symbols can be found in the Introduction (see pages vi to x).

1.0 | Physiology and psychology of acute pain

Applied physiology of acute pain

1. High pain-related fear avoidance beliefs in patients with back pain of less than 6 months duration are associated with poor outcomes, which may be improved by treatment approaches aimed at fear avoidance (**U**) (**Level I** [PRISMA]).
2. There is a significant association between high levels of catastrophising in acute and subacute back pain and pain and disability at later points of time (**U**) (**Level III-2 SR**).
3. Psychological factors associated with poor postoperative pain control are in particular anxiety (state and trait) and catastrophising, but also expectation of pain, depression, negative affect and neuroticism/psychological vulnerability (**S**) (**Level IV SR** [PRISMA]).
4. There is significant association between anxiety, pain catastrophising (**U**) (**Level III-2 SR**), depression, psychological vulnerability and stress (**U**) (**Level IV SR**) and the subsequent development of chronic postsurgical pain.
5. Preoperative anxiety and depression are associated with an increased number of PCA demands and dissatisfaction with PCA (**U**) (**Level IV**).

☑ Pain is an individual, multifactorial experience influenced by culture, previous pain events, beliefs, mood and ability to cope (**U**).

Placebo and nocebo effects in acute pain

1. Responses to placebo across all clinical conditions are small but consistently positive. They are more prominent, although highly variable in magnitude, in studies of pain (**U**) (**Level I** [Cochrane Review]).
2. Nocebo effects in studies of pain are of moderate to large size and of high variability (**U**) (**Level I** [PRISMA]).
3. Trials aimed at studying placebo effects demonstrate larger placebo effects than those assessing responses in placebo-control groups (**U**) (**Level I** [QUOROM]).
4. Analgesic placebo effects are based upon multiple neurobiological mechanisms, including involvement of endogenous opioid, cholecystokinin (**U**) (**Level II**), endogenous cannabinoid systems (**U**)(**Level III-1**) and genotype (**N**) (**Level III-2**).
5. Analgesic placebo effects are based upon multiple psychological determinants including expectancy, classical conditioning and social and observational learning (**S**) (**Level II**).
6. Placebo and nocebo effects have significant influence on the efficacy of analgesics (**U**) (**Level II**).

☑ Placebo effects are the consequence of the psychosocial context (or treatment ritual) on the patient's mind, brain and body (**U**).

☑ Placebo effects occur in routine clinical care even when no traditional placebo is given. The outcome of a treatment is attributable to both the treatment itself and the contextual (or placebo) component (**U**).

☑ Nocebo effects occur in routine clinical care and are seen as an increased pain response to a painful stimulus or the development of adverse effects not caused by, or separate from, the intervention (**U**).

☑ Ethical harnessing of placebo and minimisation of nocebo effects will improve response to clinical management interventions (**U**)

Progression of acute to chronic pain

1. Perioperative IV ketamine reduces the incidence of chronic postsurgical pain in selected procedures (**S**) (**Level I** [Cochrane Review]).
2. Following thoracotomy, epidural analgesia reduces the incidence of chronic postsurgical pain (**S**) (**Level I** [Cochrane Review]).
3. Following breast cancer surgery, paravertebral block (**S**), local infiltration (**N**) (**Level I** [Cochrane Review]) and IV lidocaine reduce the incidence of chronic postsurgical pain (**N**) (**Level I** [PRISMA]).
4. For iliac crest bone graft harvest, continuous local anaesthetic infiltration reduces the incidence of chronic postsurgical pain (**N**) (**Level I** [Cochrane Review])
5. Pregabalin reduces the incidence of chronic postsurgical neuropathic pain, but does not affect non-neuropathic chronic postsurgical pain (**N**) (**Level I** [PRISMA]).
6. Sparing of the intercostobrachial nerve during mastectomy does not decrease chest wall hypersensitivity (**U**) (**Level I** [PRISMA]).
7. Cryoanalgesia of the intercostal nerves at the time of thoracotomy results in no improvement in acute pain but an increase in chronic pain (**U**) (**Level I**).
8. There is significant association between anxiety, pain catastrophising (**U**) (**Level III-2 SR**), depression, psychological vulnerability and stress (**U**) (**Level IV SR**) and the subsequent development of chronic postsurgical pain.
9. Other risk factors that predispose to the development of chronic postsurgical pain include the severity of presurgical chronic pain and postsurgical acute pain and intraoperative nerve injury (**U**) (**Level IV SR**).
10. Spinal anaesthesia in comparison to general anaesthesia reduces the risk of chronic postsurgical pain after hysterectomy and Caesarean section (**U**) (**Level III-2**).
11. Chronic postsurgical pain is common and may lead to significant disability (**S**) (**Level IV**).
12. Chronic postsurgical pain often has a neuropathic component (**S**) (**Level IV**).

☑ Gabapentin has no demonstrated effect in preventing chronic postsurgical pain; considerable uncertainty exists regarding efficacy with contradictory meta-analyses of a few, usually small, studies with a large degree of heterogeneity (**Q**).

☑ Implementation of transitional pain services may help manage the complex issues of prolonged postoperative opioid use and chronic postsurgical pain (**N**).

Pre-emptive and preventive analgesia

Pre-emptive analgesia

1. The timing of opioid administration (preincision rather than postincision) may reduce further opioid consumption over 24 h, but has no effect on pain scores **(N)** (**Level I** [Cochrane Review])
2. Pre-emptive use of paracetamol across a range of procedures reduces pain scores up to 2 h, opioid consumption for up to 24 h and postoperative nausea and vomiting (**N**) (**Level I** [PRISMA]).
3. Pre-emptive epidural analgesia has a significant effect on postoperative pain relief (**S**) (**Level I**).

Preventive analgesia

4. Epidural, regional and systemic local anaesthetic administration shows preventive analgesic effects in reducing chronic postsurgical pain (**S**) (**Level I** [Cochrane Review])
5. NMDA-receptor antagonists (ketamine) reduce the incidence of chronic postsurgical pain in selected procedures (**S**) (**Level I** [Cochrane Review]).

☑ In clinical trials assessing acute postoperative pain for many systemic medicines, the range of doses administered, the variable durations of follow-up and variable half-lives following infusion or repeated dosing means that "early" preventive effects, although possible, are difficult to discern from persistence of direct pharmacological effects (**U**).

Adverse physiological effects of acute pain

1. Recognition of the importance of postoperative rehabilitation including pharmacological, physical, psychological and nutritional components has led to enhanced recovery (**U**) (**Level I** [PRISMA]).

☑ Acute pain and injury of various types are inevitably interrelated and, if severe and prolonged, the injury response becomes counterproductive and can have adverse effects on outcome (**U**).

Adverse psychological effects of acute pain

1. Postoperative delirium is exacerbated by unrelieved acute pain and by overuse of sedating analgesics, in particular opioids (**N**) (**Level IV**).

☑ Failure to relieve acute pain can lead to psychological distress (**N**).

Genetics and acute pain

1. CYP2D6 polymorphisms affect plasma concentrations of active metabolites of codeine, oxycodone and tramadol with variable effects on analgesic efficacy (**U**) (**Level II**).
2. The mu opioid receptor OPRM1 polymorphism is unlikely to be clinically relevant as a single gene mutation in Caucasian populations and is more likely to be of clinical relevance in Asian populations (**U**) (**Level III-2 SR**).
3. CYP2D6 ultrarapid metabolisers are at increased risk of codeine and tramadol toxicity (**U**) (**Level IV**).

☑ Genetic polymorphisms contribute to the wide interindividual variability in plasma concentrations of a given dose of methadone (**U**).

2.0 | Assessment and measurement of pain and pain treatment

Assessment

1. There is good correlation between the visual analogue and verbal numerical rating scales (**S**) (**Level I**).
2. Regular assessment of pain leads to improved acute pain management (**U**) (**Level III-3**).
3. Appropriate assessments (including screening tools) are required to determine the presence of neuropathic pain (**N**) (**Level III-2**).

☑ Functional outcomes rather than pain scores alone should be used to guide acute pain management, including non-pharmacological approaches (**N**).

☑ Self-reporting of pain should be used whenever appropriate as pain is by definition a subjective experience (**U**).

☑ The pain measurement tool chosen should be appropriate to the individual patient and the clinical context (eg intensive care, ward, community). Developmental, cognitive, emotional, language and cultural factors should be considered (**U**).

☑ Scoring should incorporate different components of pain including the functional capacity of the patient. In the postoperative patient, this should include static (rest) and dynamic (eg pain on sitting, coughing) pain (**U**).

☑ Uncontrolled or unexpected pain requires a reassessment of the diagnosis and consideration of alternative causes for the pain (eg new surgical/ medical diagnosis, neuropathic pain) (**U**).

Outcome measures in acute pain management

1. Assessment of pain relief (with total pain relief [TOTPAR]) may be more sensitive to treatment effects than assessment of intensity (with summed pain intensity difference [SPID]) (**N**) (**Level I** [PRISMA]).

☑ Multiple outcome measures are required to adequately capture the complexity of the pain experience and how it may be modified by pain management interventions (**U**).

3.0 | Provision of safe and effective acute pain management

Education

1. There is no good evidence in favour of general education for acute neck pain having significant effects on any relevant outcomes (**U**) (**Level I** [Cochrane Review]).
2. Short educational interventions in acute whiplash injury reduce pain and disability and enhance recovery and mobility (**U**) (**Level I** [PRISMA])
3. There is limited evidence that preoperative education may lead to small improvements in postoperative outcomes such as pain, preoperative and postoperative anxiety, but not in analgesic requirements (**Q**) (**Level I** [PRISMA]).

4. General “biomedical” education in patients with acute back pain does not reduce pain or improve other outcomes (**S**) (**Level I**); however, education using a “biopsychosocial/ neuroscience” approach reduces a composite of anxiety, fear, worry, distress and healthcare utilisation (**N**) (**Level I** [PRISMA]).
5. Targeted reassurance in acute back pain by physicians in primary care can result in improved changes in psychological factors such as fear, worry, anxiety, catastrophisation and healthcare utilisation (**U**) (**Level I** [PRISMA].
6. Preoperative education improves patient or carer knowledge of pain and encourages a more positive attitude towards pain relief (**U**) (**Level II**).
7. Specific pain neuroscience education in specific surgical settings may result in less healthcare utilisation (**U**) (**Level II**).
8. Written information given to patients is better than verbal information given at the time of the interview (**S**) (**Level II**).
9. Educational interventions in cancer pain patients improve knowledge, attitudes and pain control (**U**) (**Level III-1 SR**).
10. While evidence for the benefit of patient education in terms of better pain relief is inconsistent, structured preoperative education may be better than routine information (**U**) (**Level III-2**).
11. Staff education and the use of guidelines improve pain assessment, pain relief and prescribing practices (**S**) (**Level III-3**).
12. Pain psychoeducation undertaken before surgery (pre-emptive) or throughout the perioperative period (preventive) is an underutilised component of multimodal analgesia which may reduce pain intensity, analgesic use, length of stay, return to the emergency department, patient anxiety and possibly chronic postsurgical pain (**N**) (**Level IV SR**).
13. Pain score documentation improves with various forms of nursing education, but the impact of this behaviour change has not been adequately assessed (**N**) (**Level IV SR**).
14. Pain medicine education in medical school curricula is restricted in scope and content (**N**) (**Level IV SR**).

☑ Successful management of acute pain requires close liaison between all personnel involved in the care of the patient (**U**).

☑ More effective acute pain management will result from appropriate education and organisational structures for the delivery of pain relief rather than the analgesic techniques themselves (**U**).

Organisational requirements

1. Implementation of an acute pain service may improve pain relief and reduce the incidence of adverse effects (**U**) (**Level III-3**).
2. Even “simple” techniques of pain relief can be more effective if attention is given to education, documentation, patient assessment and provision of appropriate guidelines and policies (**U**) (**Level III-3**).

3. Implementation of root-cause analysis to follow up critical incidents improved the safety of patients under care of an acute pain service (**U**) (**Level III-3**).

☑ Successful management of acute pain requires close liaison between all personnel involved in the care of the patient (**U**).

☑ More effective acute pain management will result from appropriate education and organisational structures for the delivery of pain relief rather than the analgesic techniques themselves (**U**).

☑ Appropriate institutional support and engagement is important for the effective implementation of an acute pain service (**U**).

☑ Procedure-specific analgesic protocols can help optimise analgesia for the individual patient while reducing adverse effects (**U**).

☑ The adoption of individualised care pathways (eg SCAMPS) can improve patient outcomes and reduce clinical variation (**N**).

☑ The benefit of an acute pain service can be enhanced when acute pain management is integrated into the pre, intra and postoperative periods (**N**).

☑ The recruitment of patients 'at-risk' for persistent pain and/or excessive opioid use into a post-discharge treatment service for early review can improve outcomes (**N**).

☑ Appropriately designed, implemented and integrated Electronic Medical Records (EMR) can improve the standards of clinical care (**N**).

Economic considerations in acute pain management

1. Long term economic consequences from the progression of acute to chronic postsurgical and post-traumatic pain can be significant (**S**) (**Level IV**).
2. Strategies to optimise acute and subacute pain management (including involvement of transitional pain services) may reduce the economic burden of chronic pain and inappropriate prescription opioid use (**N**) (**Level IV**).
3. The early pattern of prescription opioid use after surgery may increase the risk of chronic use with significant direct and indirect economic costs (**N**) (**Level IV**).
4. Patients' willingness to pay for good pain relief is high (**S**) (**Level IV**).
5. Costs from PCA errors can be considerable; the most common high cost errors arise from staff communication error and operator error (**S**) (**Level IV**).

☑ There are different measures of economic assessment and analysis used in healthcare; no one method is the most appropriate (**U**).

☑ Prescription drug monitoring may reduce the economic burden through its impact on inappropriate opioid prescribing (**N**).

4.0 | Analgesic medicines

Paracetamol

1. Paracetamol is an effective analgesic for acute pain; the incidence of adverse effects is comparable to placebo (**U**) (**Level I** [Cochrane Review]).
2. Paracetamol given in addition to PCA opioids reduces opioid consumption but does not result in a decrease in opioid-related adverse effects (**U**) (**Level I**).
3. Hepatotoxicity with therapeutic doses of paracetamol is extremely rare (**U**) (**Level IV**) and not associated with alcohol consumption (**U**) (**Level I** [PRISMA]).

☑ Emerging evidence suggests that maternal paracetamol use may influence premature closure of the fetal ductus arteriosus **(N).**

Nonselective NSAIDs and coxibs

Efficacy of systemic NSAIDs

1. Nonselective NSAIDs are effective in the treatment of acute postoperative pain, renal colic, migraine, primary dysmenorrhoea (**S**) (**Level I** [Cochrane Review]), acute muscle injury (**N**) (**Level I** [PRISMA]), chronic low-back pain (**U**) (**Level I** [PRISMA]) and acute ankle sprain (**U**) (**Level I**).
2. Coxibs are as effective as nonselective NSAIDs in the treatment of acute pain (including postoperative pain) (**S**) (**Level I** [Cochrane Review]), chronic low-back pain (**U**) (**Level I** [PRISMA]) and osteoarthritis of the knee (**N**) (**Level I** [PRISMA]).
3. Nonselective NSAIDs given in addition to paracetamol improve analgesia compared with either medicine given alone (**S**) (**Level I**), in particular ibuprofen combined with paracetamol (**U**) (**Level I** [Cochrane Review]).
4. The risk-benefit ratio for coxibs as a discharge medication after orthopaedic surgery is superior to that for nonselective NSAIDs (**U**) (**Level I** [PRISMA]).
5. Nonselective NSAIDs given in addition to PCA opioids reduce opioid consumption and the incidence of nausea and vomiting (**U**) (**Level I**).
6. Coxibs given in addition to PCA opioids reduce opioid consumption but do not result in a decrease in opioid-related adverse effects (**U**) (**Level I**), except after total knee arthroplasty, where they reduce pain scores and adverse effects and improve outcomes (**U**) (**Level I**).
7. Celecoxib given as a single pre-operative dose is effective at reducing opioid usage, pain scores at 24 hours and postoperative nausea and vomiting (**N**) (**Level I**).

Adverse effects of systemic NSAIDs

8. In patients with normal preoperative renal function nonselective NSAIDs slightly increase serum creatinine, but effects on acute kidney injury and need for renal replacement therapy are uncertain due to lack of evidence (**W**) (**Level I** [Cochrane Review]).
9. Nonselective NSAIDs may increase the risk of any bleeding-related outcome after tonsillectomy in adults (**U**) (**Level I**); however, not in paediatric patients (**U**) (**Level I** [Cochrane Review]) except in a large non-inferiority RCT where need for surgical intervention was increased with ibuprofen versus paracetamol (**Q**) (**Level II**). There is an increase in bleeding complications with aspirin in adults and children (**U**) (**Level I**) and with ketorolac in adults only (**U**) (**Level III-2** [PRISMA]).

10. Nonselective NSAIDS, but not coxibs, may cause bronchospasm in individuals known to have NSAID-exacerbated respiratory disease (**U**) (**Level I** [PRISMA]).
11. Coxibs and nonselective NSAIDs exert individual (non-class) adverse effects on the cardiovascular system with rofecoxib appearing to be worse than other coxibs and nonselective NSAIDs (**N**) (**Level I**). Celecoxib is no worse than naproxen or ibuprofen (**N**) (**Level II**) and better than ibuprofen when combined with aspirin (**N**) (**Level II**).
12. Short-term use of parecoxib (**S**) (**Level I**) and other NSAIDs (**U**) (**Level III-2**) compared with placebo does not increase the risk of cardiovascular adverse effects after noncardiac surgery.
13. Use of parecoxib followed by valdecoxib after coronary artery bypass graft surgery increases the incidence of cardiovascular and cerebrovascular effects and is therefore contraindicated (**U**) (**Level I**).
14. Perioperative nonselective NSAIDs may increase the risk of minor and major bleeding after surgery compared with placebo (**W**) (**Level I**).
15. Coxibs do not impair platelet function and are not associated with increased perioperative blood loss (**S**) (**Level I**).
16. In patients with normal renal function, parecoxib perioperatively does not increase renal failure (**N**) (**Level I**).
17. NSAIDs hasten bowel recovery after colorectal surgery (**N**) (**Level I**).
18. With regard to renal function, celecoxib and naproxen are safer than ibuprofen with long-term use (**N**) (**Level II**).
19. Short-term use (5–7 days) of coxibs results in gastric ulceration rates similar to placebo and lower than nonselective NSAIDs (**U**) (**Level II**).
20. The cardiovascular protective effects of low-dose aspirin are reduced by concomitant administration of some NSAIDs, in particular ibuprofen (**S**) (**Level II**).
21. Nonselective NSAIDs, but not coxibs increase the risk of anastomotic leak after colorectal surgery (**N**) (**Level III-2**).
22. Short term use of ketorolac or ibuprofen do not increase bone healing complications in children undergoing posterior spinal fusion, osteotomy, or fractures managed surgically (**S**) (**Level III-3**) or conservatively (**N**) (**Level III-3**).
23. Chronic administration of nsNSAIDs or coxibs is associated with an increased risk of renal impairment (**N**) (**Level III-3 SR**).

☑ The risk of adverse renal effects of nonselective NSAIDs and coxibs may be increased in the presence of factors such as pre-existing renal impairment, hypovolaemia, hypotension and use of other nephrotoxic agents including angiotensin-converting enzyme inhibitors (**W**).

Nonsystemic administration of NSAIDs

1. Topical NSAIDs are effective in treating acute strains, sprains or sports injuries with systemic adverse effects comparable to placebo; gel formulations show superior efficacy over creams (**S**) (**Level I** [Cochrane Review]).

2. Topical NSAIDs are of limited analgesic efficacy for traumatic corneal abrasions, but reduce rescue analgesia requirements (**W**) (**Level I** [Cochrane Review]).
3. Topical NSAIDs reduce anterior chamber inflammation and thereby pain after cataract surgery (**N**) (**Level I** [PRISMA])**.**
4. The efficacy of NSAIDs for peri- or intra-articular injection as a component of local infiltration analgesia compared with systemic administration remains unclear (**U**) (**Level I** [PRISMA]).
5. Intra-articular nonselective NSAIDs may provide more effective analgesia following arthroscopy than intravenous administration (**U**) (**Level I**).
6. Mucosal administration of flurbiprofen provides long-lasting pain relief for sore throat (**N**) (**Level II**).

Opioids

Systemic opioids

1. Dextropropoxyphene has low analgesic efficacy (**U**) (**Level I** [Cochrane Review]).
2. Tramadol is an effective treatment for neuropathic pain (**S**) (**Level I** [Cochrane Review]).
3. Droperidol, metoclopramide, ondansetron, tropisetron, dolasetron, dexamethasone, cyclizine, granisetron (**U**) (**Level I** [Cochrane Review]), supplemental crystalloid infusions (**N**) (**Level I** [Cochrane Review]), palonosetron and mirtazapine (**N**) (**Level I** [PRISMA]) are effective in the prevention of postoperative nausea and vomiting.
4. PC6 acupoint stimulation by multiple techniques reduces postoperative nausea and vomiting (**S**) (**Level I** [Cochrane Review]).
5. Neurokinin-1 receptor antagonists aprepitant (**S**) (**Level I** [PRISMA]) and fosaprepitant (**U**) (**Level II**) are effective in the prevention of postoperative nausea and vomiting.
6. Intraoperative administration of the long acting opioid methadone reduces consumption of shorter acting opioids in the 24 hours after surgery (**N**) (**Level I** [PRISMA]). Safety data suggest an increased risk of opioid induced ventilatory impairment due to the long and unpredictable half-life of methadone (**N**) (**Level IV**).
7. Opioids in high doses, in particular remifentanil, can induce hyperalgesia and/or acute tolerance (**S**) (**Level I** [PRISMA]).
8. Propofol (**U**) (**Level I** [PRISMA]), NMDA-receptor antagonists (**U**) (**Level I** [QUOROM]), pregabalin (**U**) (**Level II**), nitrous oxide (**N**) (**Level II**) and gradual tapering of remifentanil dose (**N**) (**Level II**) attenuate acute tolerance and/or hyperalgesia induced by remifentanil.
9. NSAIDs, gabapentin, pregabalin, systemic lidocaine and ketamine are opioid-sparing medications and reduce opioid-related adverse effects (**S**) (**Level I** [PRISMA]).
10. Paracetamol given preoperatively and intraoperatively reduces postoperative nausea and vomiting; this effect is associated with improved analgesia, not reduced opioid requirements (**S**) (**Level I** [PRISMA]).
11. Opioid antagonists (methylnaltrexone, naloxone, naloxegol, alvimopan, axelopran, or naldemedine) are effective (more so than laxatives) and safe to treat opioid-induced constipation (**S**) (**Level I** [PRISMA]).

12. Alvimopan is an effective treatment for postoperative ileus (**U**) (**Level I** [QUOROM]).
13. Haloperidol, perphenazine and transdermal scopolamine are effective in the prevention of postoperative nausea and vomiting (**U**) (**Level I**).
14. The incidence of clinically meaningful adverse effects (nausea, vomiting) of opioids is dose-related (**U**) (**Level I**).
15. Paired combinations of $5HT_3$ antagonists, droperidol or dexamethasone provide superior prophylaxis of postoperative nausea and vomiting than either compound alone (**U**) (**Level I**).
16. Naloxone, naltrexone, droperidol (**U**), nalbuphine (**S**) (**Level I**) and ondansetron (**N**) (**Level I** [PRISMA]) are effective treatments for opioid-induced pruritus.
17. Opioids administered by PCA, in particular morphine, show higher analgesic efficacy in females than in males (**U**) (**Level I**).
18. Tapentadol has similar efficacy to conventional opioids with a reduced rate of gastrointestinal adverse effects (nausea, vomiting, constipation) (**S**) (**Level I**).
19. Tramadol has a lower risk of respiratory depression and impairs gastrointestinal motor function less than other opioids at equianalgesic doses (**U**) (**Level II**).
20. Pethidine is not superior to morphine or hydromorphone in treatment of pain of renal colic (**U**) (**Level II**).
21. Morphine-6-glucuronide is an effective analgesic (**U**) (**Level II**).
22. In the management of acute pain, one opioid is not superior to others but some opioids are better in some patients (**U**) (**Level II**).
23. High doses of methadone can lead to prolonged QT interval (**U**) (**Level II**).
24. Opioid antagonists are effective treatments for opioid-induced urinary retention (**U**) (**Level III-1**).
25. Pethidine use is associated with an increased risk of delirium in the postoperative period compared to other opioids (**S**) (**Level III-2 SR**).
26. In clinically relevant doses, there is a ceiling effect for respiratory depression with buprenorphine but not for analgesia (**U**) (**Level III-2**).
27. Tapentadol has lower rates of abuse and doctor shopping than oxycodone (**S**) (**Level III-2**).
28. Opioid-related adverse effects in the postoperative period are associated with increased inpatient mortality, length of hospital stay, costs and rates of readmission (**S**) (**Level III-2**).
29. Assessment of sedation is a more reliable way of detecting early opioid-induced ventilatory impairment than a decreased respiratory rate (**S**) (**Level III-3**).
30. The evidence for significant QT prolongation and risk of cardiac arrhythmias following low-dose droperidol, haloperidol and dolasetron is weak (**U**) (**Level III-3**).
31. Opioid-induced ventilatory impairment occurs in particular in the first 24 h after surgery and important risk factors are cardiac and pulmonary disease, obstructive sleep apnoea and use of higher opioid doses (**N**) (**Level IV SR** [PRISMA]).

32. Continuous pulse oximetry in patients receiving opioids postoperatively increases detection rate of desaturation, but continuous capnography is superior in identifying episodes of opioid-induced ventilatory impairment (**N**) (**Level IV SR** [PRISMA]).

33. In adults, patient age rather than weight is a better predictor of opioid requirements, although there is a large interpatient variation (**U**) (**Level IV**).

34. Impaired renal function and the oral route of administration result in higher levels of the morphine metabolite morphine-6-glucuronide with increased risk of sedation and respiratory depression (**U**) (**Level IV**).

34. CYP2D6 ultrarapid metabolisers are at increased risk of codeine toxicity (**N**) (**Level IV**).

☑ Opioid-induced ventilatory impairment is a more appropriate term to describe the effects of opioids on ventilation as it encompasses the central respiratory depression caused by opioids and also the depressed consciousness and the subsequent upper airway obstruction resulting from excessive opioid use (**U**).

☑ The use of pethidine and dextropropoxyphene should be discouraged in favour of other opioids (**S**).

☑ Drug interactions relevant for opioids include pharmacodynamic considerations (eg coadministration of sedative agents) and pharmacokinetic effects (eg CYP 450 enzyme inducers or inhibitors [antidepressants for CYP2D6 and antifungals, antibiotics for CYP3A4 and complementary medicines for both]) (**N**).

Neuraxial opioids

Intrathecal opioids

1. Intrathecal morphine and intrathecal fentanyl prolong spinal local anaesthetic block, with fentanyl being associated with fewer adverse effects (**U**) (**Level I** [PRISMA]).

2. Intrathecal morphine produces better postoperative analgesia than intrathecal fentanyl or sufentanil after Caesarean section (**U**) (**Level I**).

3. Intrathecal morphine doses of 300 mcg or more increase the risk of respiratory depression (**U**) (**Level I**).

Epidural opioids

4. Epidural morphine provides similar analgesia to epidural fentanyl when combined with local anaesthetic, although the incidence of nausea is greater with morphine (**U**) (**Level I** [PRISMA]).

5. Extended-release epidural morphine provides analgesia for up to 48 hours (**U**) (**Level II**), however it is associated with more respiratory depression than intravenous PCA following abdominal surgery (**U**) (**Level I**).

6. Epidural pethidine produces better pain relief and less sedation than intravenous pethidine after Caesarean section (**U**) (**Level II**).

☑ No neurotoxicity has been shown at normal clinical intrathecal doses of morphine, fentanyl and sufentanil (**U**).

☑ Neuraxial administration of bolus doses of hydrophilic opioids carries an increased risk of delayed sedation and respiratory depression compared with lipophilic opioids (**U**).

Peripheral opioids

1. Intra-articular morphine (1 mg) following knee arthroscopy does not improve analgesia compared with placebo (**S**) (**Level I** [Cochrane Review]).
2. Intra-articular morphine/bupivacaine following knee arthroscopy compared to bupivacaine alone improves analgesia without increasing adverse effects (**N**) (**Level I** [PRISMA]).
3. Perineural buprenorphine/local anaesthetic for peripheral nerve blocks compared to local anaesthetic and to systemic buprenorphine/local anaesthetic prolongs duration of analgesia (**N**) (**Level I** [PRISMA]).
4. Perineural tramadol/local anaesthetic for brachial plexus block compared to local anaesthetic alone prolongs duration of analgesia (**N**) (**Level I** [PRISMA]).
5. Peripherally applied opioids (excluding intra-articular, perineural and mucosal administration) show no clinically relevant analgesic effect (**N**) (**Level I** [PRISMA]).
6. Intra-articular tramadol/bupivacaine following knee arthroscopy compared to bupivacaine alone improves analgesia without increasing adverse effects (**N**) (**Level I**).
7. Morphine mouthwash may have analgesic effects in chemotherapy-induced mucositis (**N**) (**Level II**).
8. Evidence for intra-articular analgesic administration is inconclusive for temporomandibular joint arthrocentesis (**N**) (**Level IV SR** [PRISMA]).

Local anaesthetics and other membrane stabilisers

Systemic local anaesthetics and membrane stabilisers

1. Perioperative intravenous lidocaine reduces pain and opioid requirements to a limited extent following a range of surgery types, as well as nausea, but not vomiting, incidence and duration of ileus and length of hospital stay (**W**) (**Level I** [Cochrane Review]).
2. In breast surgery, perioperative lidocaine infusion does not improve pain scores for up to 72 hours, but is associated with lower acute opioid requirements and less chronic postsurgical pain at 3 to 6 months (**N**) (**Level I** [PRISMA])
3. Perioperative intravenous lidocaine has a preventive analgesic effect (extending beyond 5.5 half-lives of lidocaine, ie > 8 hrs after cessation of administration) after a wide range of operations (**U**) (**Level I**).
4. Both intravenous lidocaine and mexiletine are effective in the treatment of chronic neuropathic pain (**U**) (**Level I** [Cochrane Review]); however, guidelines advise against the use of mexiletine for this indication (**N**) (**GL Level I** [PRISMA]).
5. Perioperative IV lidocaine reduces chronic postsurgical pain at 3 months compared to placebo (**N**) (**Level I** [PRISMA]).

☑ The optimal and safe dose and duration of perioperative intravenous lidocaine infusions has yet to be clearly established (**N**).

☑ Based on the experience in chronic neuropathic pain states, it would seem reasonable to use membrane stabilisers including systemic lidocaine in the management of acute neuropathic pain (**U**).

☑ The role and safety of IV lidocaine for analgesia in the emergency department still requires clarification (**N**).

Regional local anaesthetics

1. Lidocaine intrathecal is more likely to cause transient neurologic symptoms than bupivacaine, prilocaine and procaine (**S**) (**Level I** [Cochrane Review NMA]).
2. Local anaesthetics have chondrotoxic effects on articular cartilage, with ropivacaine the least toxic (**N**) (**Level I** [PRISMA]).
3. Wound infiltration with liposomal preparations of bupivacaine is no more effective than ropivacaine or plain bupivacaine for analgesic outcomes up to 48 hours (**N**) (**Level I** [PRISMA]).
4. The quality of epidural analgesia with local anaesthetics is improved with the addition of opioids (**U**) (**Level I**).
5. Ultrasound guidance reduces the risk of vascular puncture during the performance of regional blocks (**S**) (**Level I**).
6. Local anaesthetic systemic toxicity is reduced by the use of ultrasound guidance for regional anaesthesia (**S**) (**Level I**).
7. Continuous perineural infusions of lidocaine result in less effective analgesia and more motor block than long-acting local anaesthetic agents (**U**) (**Level II**).
8. There are no consistent differences between ropivacaine, levobupivacaine and bupivacaine in terms of quality of analgesia or motor block, when given in low doses for regional analgesia (epidural and peripheral nerve block) (**U**) (**Level II**).
9. Cardiovascular and central nervous system toxicity of the stereospecific isomers ropivacaine and levobupivacaine is less severe than with racemic bupivacaine (**U**) (**Level II**).
10. Local anaesthetic systemic toxicity is increased in paravertebral and upper limb blocks, with the use of lidocaine and higher doses of local anaesthetics (**U**) (**Level IV**).
11. Lipid emulsion is effective in resuscitation of circulatory collapse due to local anaesthetic toxicity (**S**) (**Level IV SR**); however, uncertainties relating to dosage, efficacy and adverse effects still remain; therefore, it is appropriate to administer lipid emulsion only once ventilatory support has begun and convulsions are controlled (**S**) (**Level IV**).

☑ Case reports following accidental overdose with ropivacaine, levobupivacaine and bupivacaine suggest that resuscitation is less likely to be successful with bupivacaine (**U**).

Inhalational agents

1. Nitrous oxide has some analgesic efficacy in labour pain (**U**), increases maternal adverse effects (nausea, vomiting, dizziness) (**U**), with no adverse effects on the newborn (**U**) (**Level I** [Cochrane Review]) and increases maternal satisfaction compared to pethidine and epidural analgesia (**U**) (**Level IV SR**).
2. Nitrous oxide has equivalent effectiveness and more rapid recovery compared with intravenous sedation in patients having lower gastrointestinal endoscopy (**U**) (**Level I**).

3. Methoxyflurane, in low doses, is an effective analgesic with rapid onset in the prehospital setting, and a range of procedures in the hospital setting (**U**) (**Level II**) with good safety data (**S**) (**Level IV**); it may have comparable efficacy to nitrous oxide (**N**) (**Level I** [NMA]), but is inferior to IV morphine and IN fentanyl (**N**) (**Level III-2 SR**).
4. Nitrous oxide is an effective analgesic agent in a variety of other acute pain situations (**U**) (**Level II**).
5. Intraoperative use of nitrous oxide reduces the incidence of chronic postsurgical pain in Asian populations (**N**) (**Level II**).
6. Subacute combined degeneration of the spinal cord, myelopathy and generalised demyelinating polyneuropathy are rare but potentially serious complications of nitrous oxide use including in those abusing nitrous oxide (**S**) (**Level IV SR**).
7. Vitamin B_{12} deficiency (identified by vitamin B_{12} level $\leq$74 pmol/L and MCV >100 fL) and age $\geq$40 years are relevant risk factors in nitrous oxide neurotoxicity; total nitrous oxide exposure may not be a risk factor (**N**) (**Level IV SR**).
8. Early supplementation with Vitamin B_{12} in subacute combined degeneration of the spinal cord exacerbated by nitrous oxide use improves neurological recovery (**N**) (**Level IV SR**).

☑ In patients receiving nitrous oxide repeatedly, supplementation with vitamin B_{12}, methionine and folic or folinic acid is a consideration, in particular in those with risk factors (**Q**).

☑ If nitrous oxide is used with other sedative or analgesic agents, appropriate clinical monitoring should be used (**U**).

NMDA-receptor antagonists

Systemic NMDA-receptor antagonists

1. Perioperative IV ketamine reduces opioid consumption, pain intensity and postoperative nausea and vomiting compared to placebo (**S**) (**Level I** [Cochrane Review]); similar outcomes are achieved when ketamine is added to an opioid in a PCA pump (**S**) (**Level I** [PRISMA]).
2. Perioperative IV ketamine reduces the incidence of chronic postsurgical pain in selected procedures (**S**) (**Level I** [Cochrane Review]).
3. NMDA-receptor antagonists reduce the development of acute tolerance/opioid-induced hyperalgesia associated with remifentanil use (**S**) (**Level I** [PRISMA]).
4. IV ketamine reduces ischaemic pain intensity in critical limb ischaemia (**N**) (**Level I** [PRISMA]).
5. IV magnesium as an adjunct to morphine analgesia has an opioid-sparing effect and improves pain scores (**S**) (**Level I** [PRISMA]).
6. IV magnesium is effective in treatment of acute migraine attacks (**N**) (**Level I** [PRISMA]).
7. IV ketamine is effective in the treatment of neuropathic pain following spinal cord injury (**U**) (**Level I**).
8. Morphine/ketamine compared with higher doses of morphine alone improves analgesia and reduces sedation and postoperative nausea and vomiting in postoperative patients (**U**) (**Level I**).

9. IV ketamine does not increase intracranial pressure or reduce cranial perfusion pressure compared to opioids (**U**) (**Level I**).
10. Perioperative dextromethorphan reduces opioid consumption and pain intensity compared to placebo (**N**) (**Level I**)
11. Ketamine is a safe and effective analgesic in the prehospital setting (**U**) (**Level II**).
12. Ketamine reduces postoperative pain and opioid requirements in opioid-tolerant patients (**S**) (**Level II**).
13. IV magnesium extends the duration of sensory block with spinal anaesthesia and reduces subsequent postoperative pain (**N**) (**Level II**).

☑ Increasing rates of ketamine abuse are reported, in particular from South-East Asia and China (**S**).

☑ Ketamine toxicity leads to cognitive impairment and abuse to chronic organ toxicity (bladder, liver) (**U**).

Regional NMDA-receptor antagonists

1. Neuraxial magnesium reduces pain intensity and analgesic requirements after Caesarean section (**N**) (**Level I** [PRISMA].
2. Oral topical magnesium or ketamine (as gargle or lozenge) reduce the incidence of postoperative sore throat (**N**) (**Level I** [PRISMA].
3. Intra-articular magnesium improves analgesia after arthroscopic surgery compared to placebo (**N**) (**Level I** [PRISMA].
4. Magnesium added to local anaesthetics in peripheral nerve blocks prolongs sensory block and analgesic effects (**N**) (**Level I** [PRISMA].
5. Epidural ketamine (without preservative) added to opioid-based epidural analgesia regimens improves pain relief without reducing adverse effects (**U**) (**Level I**).
6. Caudal ketamine in children, in combination with local anaesthetic or as the sole medication, improved and prolonged analgesia with few adverse effects (**U**) (**Level I**).

☑ Variable results for regional and topical administration of ketamine and magnesium may reflect systemic effects (**N**).

Antidepressant medicines

1. In chronic neuropathic pain and fibromyalgia, tricyclic antidepressants and serotonin–noradrenaline-reuptake inhibitor are effective analgesics (**W**) and more effective than selective serotonin-reuptake inhibitors (**U**) (**Level I** [Cochrane Review]).
2. Tricyclic antidepressants are effective in the treatment of chronic headaches (**U**) (**Level I** [PRISMA]).
3. Duloxetine is as effective as other first-line treatments for pain and disability of osteoarthritis (**U**) (**Level I**).
4. Some antidepressants, in particular duloxetine, may be effective in the treatment of chronic low-back pain (**U**) (**Level I**).

5. Perioperative serotonin-noradrenaline reuptake inhibitors reduce acute pain and opioid requirements in a limited number of studies (**U**) (**Level II**).

☑ Based on the experience in chronic neuropathic pain states, it would seem reasonable to use tricyclic antidepressants and serotonin–noradrenaline-reuptake inhibitors in the management of acute neuropathic pain (**U**).

☑ To minimise adverse effects, it is advisable to initiate treatment with tricyclic antidepressants at low doses (**U**).

Anticonvulsant medicines

1. Alpha-2-delta ligands (gabapentinoids) are the only anticonvulsants with proven efficacy in the treatment of chronic neuropathic pain (**S**) (**Level I** [Cochrane Review]).
2. Pregabalin is the only anticonvulsant with proven but limited efficacy in chronic pain due to fibromyalgia (**S**) (**Level I** [Cochrane Review]).
3. Perioperative alpha-2-delta ligands (gabapentinoids) reduce postoperative pain and opioid requirements, in particular after more painful surgery (**Q**) and reduce the incidence of postoperative nausea and vomiting (**S**) as well as pruritus (**S**), but increase the risk of sedation (**S**) and visual disturbances (**N**) (**Level I** [PRISMA]).
4. Overdose toxicity of alpha-2-delta ligands is increased when taken in combination with other agents that cause sedation, particularly opioids (**N**) (**Level III-2**).
5. Alpha-2-delta ligands have the potential for misuse and abuse, in particular in patients with opioid use disorder or psychiatric comorbidity (**N**) (**Level IV SR**).

☑ Based on the experience in chronic neuropathic pain states, it would seem reasonable to use alpha-2-delta ligands in the management of acute neuropathic pain (**U**).

Alpha-2 agonists

Systemic alpha-2 agonists

1. Alpha-2 agonists such as clonidine are more effective than placebo in the management of opioid-withdrawal symptoms (**U**) (**Level I** [Cochrane Review]).
2. The perioperative use of clonidine systemically (excluding transdermal administration) does not reduce pain intensity (at 24 or 48 hours) (**Q**) (**Level I**) but reduces opioid consumption and postoperative nausea and vomiting versus placebo (**Q**) (**Level I** [PRISMA]).
3. The perioperative use of the systemic dexmedetomidine reduces postoperative pain intensity, opioid consumption and requirements for rescue analgesia (**S**) without effect on postoperative nausea and vomiting (**N**) (**Level I** [PRISMA]).
4. The IV administration of dexmedetomidine combined with intrathecal local anaesthetic prolongs time to first analgesic request (**N**) (**Level I** [PRISMA]).

Regional alpha-2 agonists

1. Neuraxial clonidine improves duration and quality of analgesia and is opioid sparing when used as an adjuvant to neuraxial local anaesthetics (in particular after Caesarean section) (**S**) (**Level I** [PRISMA]) or to morphine (**U**) (**Level I** [PRISMA]), but increases the risk of hypotension and sedation (**N**) (**Level I** [PRISMA]).

2. Neuraxial dexmedetomidine improves duration and quality of analgesia when used as an adjuvant to neuraxial local anaesthetics (**S**) (**Level I** [PRISMA]).
3. Intrathecal adrenaline (epinephrine) when combined with local anaesthetic, but not with intrathecal opioids, prolongs analgesia duration (**U**) (**Level I** [PRISMA]).
4. Dexmedetomidine when added to local anaesthetics for peripheral nerve blocks improves duration and quality of analgesia, but is associated with increased hypotension and bradycardia (**S**) (**Level I** [PRISMA]).
5. Intra-articular clonidine reduces pain scores for 4 hours, need for rescue analgesia and incidence of nausea, but increases hypotension (**N**) (**Level I** [PRISMA])
6. Clonidine improves duration of analgesia and anaesthesia when used as an adjuvant to local anaesthetics for peripheral nerve and plexus blocks but is associated with increased hypotension and bradycardia (**U**) (**Level I**).
7. Dexmedetomidine added to intravenous regional anaesthesia improves and prolongs analgesia (**U**) (**Level II**).
8. Epidural adrenaline (epinephrine) in combination with a local anaesthetic improves the quality of postoperative thoracic epidural analgesia (**U**) (**Level II**).

☑ The benefits of perineural adjuvant administration of alpha-2-agonists over systemic administration remains unclear (**N**).

Salmon calcitonin and bisphosphonates

1. Bisphosphonates reduce bone pain associated with metastatic breast cancer (**U**), multiple myeloma (**S**) and Paget's disease (**N**) (**Level I** [Cochrane Review]), but have no beneficial effect for knee arthritis (**N**) (**Level I**).
2. Salmon calcitonin reduces pain and improves mobilisation in the acute phase after osteoporosis-related vertebral compression fractures (**U**) (**Level I** [PRISMA]).
3. Bisphosphonates reduce pain in patients with CRPS Type 1 in the early phase of the disease (**N)** (**Level I**).
4. Salmon calcitonin reduces acute, but not chronic, phantom limb pain (**U**) (**Level II**).
5. Pamidronate reduces pain associated with acute osteoporotic vertebral compression fractures (**U**) (**Level II**).

Cannabis, cannabinoids and cannabimimetics

1. Adverse effects including dizziness, cognitive changes and psychiatric symptoms (eg psychosis) may limit the usefulness of cannabinoids in pain treatment (**S**) (**Level I** [Cochrane Review]).
2. Current evidence does not support the use of cannabinoids in acute pain management (**S**) (**Level I** [PRISMA]).
3. Smoking cannabis has short-term efficacy in neuropathic pain in patients with HIV/AIDS, although potential study bias means that this is not recommended as routine treatment (**Q**) (**Level I** [PRISMA]).

4. Cannabinoids appear to be mildly effective when used in the treatment of pain and spasticity associated with multiple sclerosis and HIV (**W**) (**Level III-2 SR** [PRISMA]).
5. Smoked cannabis increases the risk of acute coronary syndrome and chronic cardiovascular disease (**N**) (**Level IV SR**).

Corticosteroids

Systemic corticosteroids

1. Mild increase in blood glucose concentration follows perioperative administration of dexamethasone (**S**) (**Level I** [Cochrane Review]) and all corticosteroids (**S**) (**Level I** [PRISMA), particularly in patients with diabetes mellitus.
2. Perioperative administration of dexamethasone (**N**) (**Level I** [Cochrane Review]) and all corticosteroids (**N**) (**Level I** [PRISMA]) does not increase the risk of infection.
3. Perioperative administration of dexamethasone reduces postoperative pain and opioid requirements to a limited extent but also reduces nausea and vomiting, fatigue, and improves the quality of recovery compared with placebo (**U**) (**Level I** [PRISMA]).
4. Preoperative dexamethasone appears to be more effective than intraoperative or postoperative administration (**U**) (**Level I** [PRISMA]).
5. Perioperative corticosteroids do not increase the risk of impaired wound healing, anastomotic leakage or postoperative haemorrhage (**N**) (**Level I** [PRISMA]).
6. A single dose of corticosteroids provides more effective and faster relief of pain from sore throat than placebo (**N**) (**Level I**) and decreases incidence and severity of sore throat after extubation when administered at induction (**N**) (**Level I** [PRISMA]).
7. Systemic dexamethasone reduces pain intensity and opioid requirements after spinal anaesthesia (**N**) (**Level I** [PRISMA].

☑ As all adverse event data on corticosteroid use in surgical populations are based to date on efficacy trials (with methodological differences), their long-term safety awaits further evaluation (**N**).

Regional corticosteroids

1. For brachial plexus blocks, addition of dexamethasone to local anaesthetic prolongs the duration of sensory and motor block and improves postoperative analgesia with only very limited benefits over systemic administration (**S**) (**Level I** [Cochrane Review]).
2. For transverse abdominis plane blocks, addition of dexamethasone to local anaesthetics prolongs the duration of sensory block, improves postoperative analgesia and PONV with no comparison to systemic administration (**N**) (**Level I** [PRISMA]).
3. After spinal surgery, epidural steroid application intraoperatively by the surgeon provides analgesic benefit up to 24 hours and reduces length of stay (**N**) (**Level I** [PRISMA]).
4. For acute radicular pain, lumbar epidural corticosteroid administration is effective for short-term relief (**S**) (**Level I** [PRISMA]).
5. Subacromial injections of corticosteroids are superior to oral NSAIDs in treating rotator cuff tendonitis (**U**) (**Level I** [QUOROM]).

6. For peripheral nerve blocks, addition of dexamethasone to local anaesthetics prolongs the duration of sensory block and improves postoperative analgesia with only limited benefits over systemic administration (**N**) (**Level II**).
7. For epidural analgesia, addition of dexamethasone improves postoperative analgesia and reduces opioid requirements (**N**) (**Level II**).
8. Addition of dexamethasone to intravenous regional anaesthesia with lidoocaine improves analgesia for up to 24 hours (**U**) (**Level II**).
9. Addition of corticosteroid to periarticular injection of local anaesthetic does not improve pain relief or range of movement following total knee arthroplasty (**U**) (**Level II**).
10. Following knee joint arthroscopy, intra-articular steroids in combination with either local anaesthetic or opioids reduce pain, analgesic consumption and duration of immobilisation (**U**) (**Level II**).
11. There is a risk of septic arthritis with intra-articular steroids (**U**) (**Level IV**).
12. Repeat epiudural steroid injections are associated with reduced bone mineral density and increased risk of vertebral fractures (**N**) (**Level IV SR).**

☑ Concerns have been raised regarding the safety of epidural steroids (**U**).

☑ There is little data in humans regarding the neurotoxicity of perineural corticosteroids (**N**).

Other regional analgesic medicines

1. Intrathecal midazolam combined with a local anaesthetic improves and prolongs analgesia and reduces postoperative nausea and vomiting (**U**) (**Level I**).
2. Intrathecal neostigmine improves perioperative and peripartum analgesia in combination with other intrathecal medications (**S**) (**Level I**) but is associated with dose-dependent significant adverse effects, in particular nausea and vomiting (**Q**) (**Level I**).
3. Epidural neostigmine combined with local anaesthetics improves postoperative and peripartum analgesia without increasing the incidence of adverse effects (**U**) (**Level I**).
4. Epidural neostigmine combined with an opioid reduces the dose of epidural opioid that is required for analgesia (**U**) (**Level I**).

Complementary and alternative medicine

1. White willow bark (*Salix alba*) and devil's claw (*Harpagophytum procumbens*) are effective in treating acute episodes of low back pain (**U**) (**Level I** [Cochrane Review])
2. A variety of complementary medicines may show efficacy in prevention and treatment of primary dysmenorrhoea based on very limited evidence (**W**) (**Level I** [Cochrane Review]), including aromatherapy (**N**) (**Level III-1 SR**).
3. Curcuminoids and extracts of Zingiberaceae may reduce pain intensity in acute and chronic pain states compared to placebo (**N**) (**Level I** [PRISMA]).
4. Oral administration of honey versus control reduces postoperative pain and analgesic use after tonsillectomy (**N**) (**Level I** [PRISMA]).

5. Vitamin C reduces postoperative opioid requirements (**N**) (**Level I** [PRISMA] and postoperative pain compared to placebo (**N**) (**Level IV SR** [PRISMA]).
6. Aromatherapy (**N**) (**Level I**), homeopathic preparations of arnica (*Arnica montana*) (**U**) (**Level I** [PRISMA]) and St John's wort (*Hypericum perforatum*) are not effective in treating acute postoperative pain (**U**) (**Level I** [QUOROM]).
7. St John's wort (*Hypericum perforatum*) induces metabolism of oxycodone reducing its plasma concentrations and efficacy (**U**) (**Level II**).

☑ There is some evidence that some complementary and alternative medicines may be effective in some acute pain states. Adverse effects and interactions with medications have been described with complementary and alternative medicines and must be considered before their use (**U**).

☑ The evidence on complementary and alternative medicines is characterised by small sample sizes and study designs prone to bias and caution is urged in interpreting results. Additionally, the safety and potential drug interactions of many complementary and alternative medicines have not been adequately assessed **(N).**

5.0 | Administration of analgesic medicines

Oral and sublingual route

1. Oral combinations of paracetamol/ibuprofen provide superior analgesia to paracetamol/codeine; both combinations are more effective than the individual medicines and have a dose-response effect (**S**) (**Level I** [Cochrane Review]).
2. Oral combinations of paracetamol/tramadol are more effective than the individual medications and have a dose-response effect (**U**) (**Level I**).
3. NSAIDs given parenterally or rectally are not more effective and do not result in fewer adverse effects than the same medicines given orally (**U**) (**Level I**).
4. The formulation of oral NSAIDs (eg fast acting [dispersible, solution or gel], sodium versus potassium salt) can greatly affect their efficacy (**N**) (**Level I**).
5. Early postoperative oral administration of paracetamol results in highly variable plasma concentrations that may remain subtherapeutic in some patients (**U**) (**Level II**). However, no difference in clinical efficacy to intravenous administration is seen in hip and knee arthroplasty (**N**) (**Level I**), Caesarean section (**N**) (**Level II**) or laparoscopic cholecystectomy (**N**) (**Level II**).

☑ Other than in the treatment of severe acute pain, and providing there are no contraindications to its use, the oral route is the route of choice for the administration of most analgesic medicines (**U**).

☑ Slow-release opioid preparations (particularly conventional opioids including transdermal fentanyl and methadone) are not recommended in general for the management of acute pain in opioid-naïve patients due to difficulties in short-term dose adjustments needed for titration, an increased risk of opioid-induced ventilatory impairment and risk of initiating long-term use (**S**). In some patients with prolonged postoperative and post-traumatic acute pain states, the use of slow-release opioid preparations may be appropriate on a short-term basis with preference for use of atypical opioids (**N**).

☑ Slow-release oral opioid preparations should only be given at set time intervals (**U**).

Intravenous route

1. Intravenous paracetamol is more effective in reducing pain, opioid consumption and PONV when given prior to versus after surgical incision (**U**) (**Level I** [PRISMA]).
2. The onset of analgesia is faster when NSAIDs are given intravenously for the treatment of renal colic (**U**) (**Level I**).
3. Continuous intravenous infusion of opioids in the general-ward setting is associated with an increased risk of respiratory depression compared with other methods of parenteral opioid administration (**U**) (**Level IV**).

☑ Titration of opioids for severe acute pain is best achieved using intermittent intravenous bolus doses as it allows more rapid titration of effect and avoids the uncertainty of medicine absorption by other routes (**U**).

Intramuscular and subcutaneous route

1. Intermittent subcutaneous morphine injections are as effective as intramuscular injections and have better patient acceptance (**U**) (**Level II**).

Transdermal route

1. Transdermal buprenorphine reduces postoperative pain with a low rate of adverse effects (**N**) (**Level II**).
2. Transdermal fentanyl (except for iontophoretic patient-controlled transdermal devices) should not be used in the management of acute pain because of safety concerns and difficulties in short-term dose adjustments needed for titration (**S**) (**Level IV**).

☑ Transdermal fentanyl preparations should not be used in opioid-naïve patients or in acute pain settings because of safety concerns and, in most countries, the lack of regulatory approval for use in other than chronic pain in opioid-tolerant patients (**S**).

Transmucosal route

1. Intranasal, sublingual and buccal fentanyl preparations are effective treatments for breakthrough pain in cancer patients (**U**) (**Level I** [Cochrane Review]) with similar efficacy to IV administration (**U**) (**Level I** [PRISMA]) and superiority to oral morphine (**U**) (**Level I**).
2. Intranasal fentanyl is an effective treatment for paediatric acute pain management, with an acceptable adverse effect profile and ease of delivery (**N**) (**Level I**).
3. Intranasal fentanyl provides faster and better analgesia for breakthrough pain in cancer patients than oral transmucosal fentanyl and fentanyl buccal tablets (**U**) (**Level I**).
4. Sublingual sufentanil delivered by a PCA device provided analgesia comparable to IV PCA opioids in a number of acute pain settings (**N**) (**Level II**).

☑ Neither transmucosal immediate-release nor transdermal fentanyl preparations should be used in the management of acute pain in opioid-naïve patients because of safety concerns and, in most countries, the lack of regulatory approval for use in other than opioid-tolerant patients (**U**).

Epidural analgesia

1. For all types of surgery, epidural analgesia provides better postoperative pain relief compared with parenteral (including PCA) opioid administration (**S**) (**Level I** [Cochrane Review]); except epidural analgesia using a hydrophilic opioid only (**U**) (**Level I**).
2. Thoracic epidural analgesia for open abdominal aortic surgery reduces pain intensity, time to tracheal extubation, time spent in the intensive care unit, rate of acute respiratory failure, myocardial infarction and gastrointestinal bleeding when compared with intravenous opioids (**S**) (**Level I** [Cochrane Review]).
3. High thoracic epidural analgesia used for coronary artery bypass graft surgery reduces postoperative pain, risk of dysrhythmias, pulmonary complications and time to extubation when compared with intravenous opioid analgesia (**Q**) (**Level I** [Cochrane Review]).
4. Thoracic epidural analgesia for thoracotomy reduces the risk of chronic postsurgical pain (**S**) (**Level I** [Cochrane Review]).
5. Thoracic epidural analgesia improves bowel recovery after abdominal surgery (including colorectal surgery) (**S**) (L**evel I** [Cochrane Review]).
6. Epidural analgesia is not associated with increased risk of anastomotic leakage after bowel surgery (**S**) (**Level I** [Cochrane Review]).
7. Epidural analgesia provided with local anaesthetics for at least 24 hours compared to systemic opioid analgesia reduces perioperative mortality and multiple morbidities (including ileus, pneumonia, respiratory depression and arrhythmias) but increases hypotension (**U**) (**Level I** [PRISMA]).
8. After laparoscopic colectomy, thoracic epidural analgesia compared to intravenous PCA reduces initial pain scores and time to first bowel opening, but length of hospital stay, total rate of complications (**S**) (**Level I** [PRISMA]), urinary tract infection rates and hospital costs are increased (**U**) (**Level III-2**).
9. Combinations of low concentrations of local anaesthetic agents and opioids for epidural analgesia provide consistently superior pain relief compared with either of the medications alone; epidural opioids alone have no advantage over parenteral opioids (**U**) (**Level I**).
10. Epidural local anaesthetic administration improves oxygenation and reduces pulmonary infections and other pulmonary complications compared with parenteral opioids (**U**) (**Level I**).
11. Chlorhexidine-impregnated dressings of epidural catheters in comparison to placebo- or povidone-iodine-impregnated dressings reduce the incidence of catheter colonisation (**U**) (**Level I**).
12. In patients with multiple rib fractures, thoracic epidural analgesia improves pain relief versus parenteral opioids (**N**) (**Level III-2 SR**), but does not reduce incidence of pneumonia and mortality (**U**) (**Level I**) and may not reduce need for ventilation (**Q**) (**Level III-2 SR**).
13. The combination of thoracic epidural analgesia with local anaesthetics and nutritional support leads to preservation of total body protein after upper abdominal surgery (**U**) (**Level II**).

14. The incidence of permanent neurological damage in association with epidural analgesia is extremely low, especially in the obstetric population, but increases with various comorbidities and risk factors; the incidence is higher where there have been delays in diagnosing an epidural haematoma or abscess (**S**) (**Level IV SR**).

15. Immediate decompression of an epidural haematoma (within 8 hours of the onset of neurological signs) increases the likelihood of partial or good neurological recovery (**S**) (**Level IV SR**).

16. Epidural abscesses present mainly with neurological deficits and back pain; they are best diagnosed with early MRI and best treated with empiric antibiotics (until abscess culture) and immediate surgical decompression when neurological deficits are present (**S**) (**Level IV SR).**

☑ The provision of epidural analgesia by continuous infusion, programmed intermittent bolus or patient-controlled administration of local anaesthetic-opioid mixtures is safe on general hospital wards, as long as supervised by an anaesthesia-based pain service with 24-hour medical staff cover and monitored by well-trained nursing staff (**U**).

☑ Prior to insertion of an epidural catheter, thorough handwashing with surgical scrub solution, the use of barrier precautions including the wearing of a cap, mask, sterile gown and gloves and use of chlorhexidine in alcohol for skin preparation are recommended; but meticulous care must be taken to avoid the chlorhexidine solution from reaching epidural space or cerebrospinal fluid (**U**).

Intrathecal analgesia

1. Intrathecal morphine improves analgesia and is opioid-sparing for up to 24 hours after major surgery including abdominal (**S**), orthopaedic (**N**), spinal (**N**) (**Level I** [PRISMA]) and cardiothoracic surgery (**N**) (**Level II**).

2. Adding intrathecal morphine to intrathecal bupivacaine/fentanyl or intrathecal bupivacaine/sufentanil prolongs pain relief after labour (**N**) (**Level I** [PRISMA]).

3. The addition of intrathecal fentanyl (**N**) (**Level I** [PRISMA]) and morphine to spinal anaesthesia prolongs time to first analgesic request after Caesarean section (**N**) (**Level I**).

4. Intrathecal morphine in comparison to peripheral regional analgesia techniques offers similar analgesic benefits, but increases adverse effects (nausea, vomiting, pruritus) after lower limb arthroplasty (**N**) (**Level I**).

5. The incidence of opioid-induced ventilatory impairment, pruritus and postoperative nausea and vomiting is higher with intrathecal morphine compared with intravenous PCA opioids (**S**) (**Level I**).

6. 6Pruritus with intrathecal opioids is dose-dependent (**N**) (**Level I**) and can be effectively prevented and treated with $5HT_3$ antagonists in non-obstetric patients, but only treated but not prevented in obstetric patients (**Q**) (**Level I**)

7. The addition of intrathecal magnesium to opioids and/or local anaesthetics results in slightly longer analgesia in non-obstetric patients (**U**) (**Level I**).

8. The addition of intrathecal clonidine to intrathecal morphine results in slightly longer analgesia and reduced opioid requirements (**U**) (**Level I**).

9. Pruritus with intrathecal opioids cannot be treated with methylnaltrexone (**N**) (**Level II**).

☑ The absence of consistent dose-responsiveness to the efficacy of intrathecal opioids and the increase in adverse effects with higher doses suggests that the lowest effective dose (typically 50-200 mcg morphine) should be used (**Q**).

☑ Patients receiving intrathecal opioids should be monitored for opioid-induced ventilatory impairment for the anticipated duration of opioid effects, eg 18 to 24 hours after intrathecal morphine (**S**).

☑ Clinical experience with morphine, fentanyl and sufentanil has shown no neurotoxicity or behavioural changes at normal clinical intrathecal doses (**U**), however caution is recommended in patients who are at risk of spinal cord ischaemia (**U**).

Other regional and local analgesic techniques

1. Topical EMLA® cream (eutectic mixture of lignocaine [lidocaine] and prilocaine) is effective in reducing the pain associated with venous ulcer debridement (**U**) (**Level I** [Cochrane Review]).
2. Transversus abdominis plane blocks provide pain relief superior to local anaesthetic infiltration for a range of abdominal surgeries (**N**) (**Level I** [PRISMA]).
3. Intraperitoneal local anaesthetic instillation after laparoscopic gastric surgery (**N**) (**Level I** [PRISMA]) and laparoscopic cholecystectomy (**U**) (**Level I**) improves postoperative pain outcomes.
4. Adductor canal block results in similar postoperative pain outcomes following total knee arthroplasty versus femoral nerve block with less quadriceps weakness, earlier mobilisation and better functional recovery (**S**) (**Level I** [PRISMA]).
5. Following thoracotomy, thoracic paravertebral block provides comparable analgesia to thoracic epidural analgesia (**U**) (**Level I**).
6. Continuous peripheral nerve block, compared with single-injection peripheral nerve block, results in improved pain control, decreased need for opioid analgesics, reduced nausea and improved patient satisfaction in some settings, in particular in the first 24 hours postoperatively (**W**) (**Level I**).
7. Femoral nerve block, either single-injection or continuous, provides better analgesia and decreased nausea compared with parenteral opioid-based techniques after total knee arthroplasty (**U**) (**Level I**).
8. Compared with opioid analgesia, continuous peripheral nerve block (regardless of catheter location) provides better postoperative analgesia and leads to reductions in opioid use as well as nausea, vomiting, pruritus and sedation (**U**) (**Level I**).
9. Blocks performed using ultrasound guidance are more likely to be successful, faster to perform, with faster onset and longer duration compared with localisation using a peripheral nerve stimulator (**U**) (**Level I**).
10. Morphine injected into the intra-articular space following knee arthroscopy does not improve analgesia compared with placebo (**U**) (**Level I**).

11. Following total knee arthroplasty, local infiltration analgesia reduces postoperative pain for up to 32 hours when compared to systemic analgesics alone; however, there is limited benefit in comparison to femoral nerve block (**U**) (**Level I**).
12. Following total hip arthroplasty, there is no additional analgesic benefit for local infiltration analgesia over conventional multimodal analgesia (**S**) (**Level I**) and peripheral nerve blocks have limited or no effect on postoperative pain (**Q**) (**Level II**).
13. Following either knee or hip arthroplasty, there is insufficient evidence to support postoperative administration of local infiltration analgesia via catheter (**U**) (**Level I**).
14. Local anaesthetic infusions or intermittent injections through wound catheters provide analgesic benefits following gynaecological and obstetric surgery, but not other abdominal or nonorthopaedic surgery (**Q**) (**Level I**).
15. Intraurethral instillation of lignocaine gel provides analgesia during flexible cystoscopy (**U**) (**Level I**).
16. The benefit of routine sciatic nerve block in addition to femoral nerve block for analgesia following total knee joint arthroplasty remains unclear (**U**) (**Level I**).
17. Continuous interscalene analgesia provides better analgesia, reduced opioid-related adverse effects and improved patient satisfaction compared with intravenous PCA or single-injection interscalene block after open shoulder surgery (**U**) (**Level II**).
18. Erector spinae plane blocks provide postoperative analgesia superior to systemic analgesia after cardiac surgery (**N**) (**Level II**) and to transverse abdominus blocks after laparoscopic cholecystectomy (**N**) (**Level II**).
19. Quadratus lumborum block reduces pain scores and opioid requirements following Caesarean section compared to placebo or control (**N**) (**Level II**).
20. Intra-articular bupivacaine infusions have been associated with chondrolysis and their use has been cautioned against (**U**) (**Level IV**).
21. Postoperative neurologic symptoms or dysfunction is often related to patient and surgical factors and the incidence of neuropathy directly related to peripheral regional anaesthesia is rare (**S**) (**Level III-3**).
22. Ultrasound guidance of regional blocks is associated with a reduced risk of local anaesthetic systemic toxicity in adults (**N**) (**Level IV**).

☑ Continuous peripheral nerve blocks carry a risk of infection; skin preparation with alcohol-based chlorhexidine and full barrier precautions (including face masks) are recommended for insertion of peripheral nerve catheters (**U**).

☑ Ultrasound-guided techniques should be practiced with a high degree of skill and care, including aseptic techniques, as they do not eliminate the risks of injury to tissues and structures, local anaesthetic systemic toxicity or site contamination (**U**).

☑ Caution should be used when considering and performing some peripheral nerve or plexus blocks in patients with impaired coagulation, in particular where the PNB is performed at a deep location that prevents external compression, should bleeding occur (**N**).

Regional analgesia and concurrent anticoagulant medications

1. Anticoagulation and coagulopathy are the two most important risk factors for the development of epidural haematoma after neuraxial block (**U**) (**Level IV**).

☑ Consensus statements of experts guide the timing and choice of regional anaesthesia and analgesia in the context of anticoagulation but do not represent a standard of care and will not substitute the risk/benefit assessment of the individual patient by the individual anaesthetist (**S**).

☑ Caution should be used when considering and performing some peripheral nerve or plexus blocks in patients with impaired coagulation, in particular where the peripheral nerve block is performed at a deep location that prevents external compression, should bleeding occur (**S**).

6.0 | Patient-controlled analgesia

1. Intravenous opioid PCA provides better analgesia than conventional parenteral opioid regimens (**S**) (**Level I** [Cochrane Review]).
2. Opioid administration by IV PCA leads to higher opioid consumption, a higher incidence of pruritus, but no difference in other opioid-related adverse effects, or hospital stay compared with traditional methods of intermittent parenteral opioid administration (**S**) (**Level I** [Cochrane Review]).
3. Patient satisfaction with intravenous PCA is higher when compared with conventional regimens (**S**) (**Level I** [Cochrane Review]).
4. The adjuvant use of ketamine with PCA opioid (in varying ratios) improves pain relief and reduces opioid consumption along with nausea and vomiting, with no increase in neurocognitive effects including hallucinations (**N**) (**Level I** [PRISMA]).
5. Iontophoretic transdermal fentanyl PCA is not as effective as intravenous morphine PCA, with more patients withdrawing from studies because of inadequate pain relief (**U**) (**Level I** [QUOROM]).
6. In settings where there are high nurse to patient ratios, there may be no difference in the effectiveness of PCA and conventional parenteral opioid regimens (**U**) (**Level I**).
7. Tramadol via intravenous PCA provides effective analgesia comparable to morphine by intravenous PCA (**U**) (**Level I**).
8. The addition of a background infusion to intravenous PCA morphine in adults increases the incidence of respiratory depression (**U**) (**Level I**) and does not improve pain relief or sleep, or reduce the number of PCA demands (**U**) (**Level II**).
9. Different opioids by intravenous PCA show different rates of adverse effects; fentanyl PCA has the least rates of sedation, nausea and vomiting while pruritus is most frequent with morphine PCA (**N**) (**Level I** [NMA]). Furthermore, on an individual patient basis, one opioid may be better tolerated than another (**U**) (**Level II**).
10. There is no analgesic benefit in adding naloxone to the PCA morphine solution; however, the incidence of nausea and pruritus may be decreased (**U**) (**Level II**).
11. Subcutaneous PCA opioids can be as effective as intravenous PCA (**U**) (**Level II**).

12. Intranasal PCA opioids can be as effective as intravenous PCA (**U**) (**Level II**).
13. In the emergency department, PCA morphine compared with IV morphine administered by nursing staff, provides more effective analgesia with more rapid onset and with higher patient satisfaction (**U**) (**Level II**).
14. The safety of PCA use can be significantly improved by hospital-wide safety initiatives (equipment, guidelines, education, monitoring) (**U**) (**Level III-3**).
15. The adoption of "smart pump" technologies in PCA design can improve documentation of patient care (**N**) (**Level III-3**), reduce programming errors and improve safety (**N**) (**Level IV SR**).
16. Operator-error, in particular programming error, remains a common safety problem with PCA useoften leading to patient harm (**S**) (**Level IV**).

☑ There is insufficient data to compare the risk of rare but serious adverse events with PCA opioid use to conventionally administered opioid analgesia (**N**).

☑ Adequate analgesia needs to be attained prior to commencement of PCA. Initial orders for bolus doses should consider individual patient factors such as a history of prior opioid use and patient age. Individual PCA prescriptions may need to be adjusted (**U**).

☑ The routine addition of antiemetics to PCA opioids is not encouraged, as it is of no benefit compared with selective administration (**U**).

☑ PCA infusion systems must incorporate anti-siphon valves and, in non-dedicated lines, antireflux valves (**U**).

☑ Drug concentrations, prescription and observation forms should be standardised to improve patient safety (**U**).

☑ The pharmacokinetics of morphine (long equilibration half-time and active metabolites) may make it less suitable for PCA use than other opioids (**U**).

☑ Pethidine, when used in PCA, may cause central nervous system toxicity due to the accumulation of norpethidine (**U**).

☑ Improved methods of patient monitoring (eg continuous pulse oximetry, continuous capnography) may offer opportunities to improve safety in at-risk patient groups (**N**).

7.0 | Nonpharmacological techniques

Psychological interventions

1. Preoperative psychological interventions may be effective at reducing pain, length of stay and negative affect after various procedures (**N**) (**Level I** [Cochrane Review]) but may not be effective after cardiac surgery (**N**) (**Level I** [Cochrane Review]).
2. Distraction (including with video, toys, music or stories) and hypnosis reduces needle related pain (**S**) and distress (**N**) in children and adolescents (**Level I** [Cochrane Review])
3. Hypnosis may reduce procedural pain and anxiety (**N**) (**Level I** [Cochrane Review]), postoperative pain (**R**) (**Level I**), postoperative anxiety (**N**) and analgesia consumption in labour (**R**) (**Level I** [Cochrane Review]).

4. Listening to music produces a small reduction in postoperative or procedural pain, analgesic requirements and emotional distress (**S**) (**Level I**); patient selected music may be more effective than clinician selected music (**N**) (**Level II**).
5. Patient education regarding the procedure or recovery may reduce postoperative pain (**Q**), preoperative anxiety (**N**) and postoperative anxiety (**N**) but does not affect analgesia use (**U**) (**Level I** [PRISMA]).
6. Training in coping methods or behavioural instruction prior to surgery reduces pain, negative affect and analgesic use (**U**) (**Level I**).
7. Relaxation techniques may reduce postoperative pain but do not reduce analgesic consumption (**S**) (**Level I**).
8. Immersive virtual reality distraction is effective in reducing pain (**S**) and anxiety (**N**) in some clinical situations (**Level III-2 SR** [PRISMA]).
9. In work injury-related acute pain, psychologically informed and workplace-oriented interventions may reduce time lost from work (**N**) (**Level III-2 SR**).

☑ Pain catastrophisation and anxiety negatively impact the postoperative experience and are risk factors for the development of chronic postsurgical pain and prolonged opioid use. Interventions aimed at reducing catastrophisation may be useful in improving patient outcomes, but retaining patient engagement with perioperative psychoeducation may also prove challenging (**N**).

☑ Preoperative psychoeducation may be cost effective from the perspective of reducing length of stay (**N**).

☑ The evidence that sensory and combined sensory-procedural information is effective in reducing procedure-related pain is equivocal and not sufficient to make recommendations (**U**).

☑ There is insufficient evidence to make a recommendation about the role of brief mindfulness-based interventions in acute pain (**N**).

Transcutaneous electrical nerve stimulation

1. Transcutaneous electrical nerve stimulation compared to sham reduces acute pain (procedural and nonprocedural) (**U**) (**Level I** [Cochrane Review]), including pain after thoracic surgery (**U**) (**Level I** [PRISMA), after total knee replacement (**N**) and in the prehospital setting (**N**) (**Level I** [PRISMA]).
2. High-frequency transcutaneous electrical nerve stimulation is effective in primary dysmenorrhoea (**U**) (**Level I** [Cochrane Review]).
3. Transcutaneous electrical nerve stimulation has no effect on pain, interventions or outcomes in labour with the exception of a reduction of reports of severe pain when applied to acupuncture points (**U**) (**Level I** [Cochrane Review]).
4. Transcutaneous electrical nerve stimulation used preventatively in migraine reduces attack frequency and medication use (**N**) (**Level I** [PRISMA])

Acupuncture and acupressure

1. Acupuncture and acupressure for labour pain may reduce pain, use of pharmacological pain relief and increase satisfaction with pain management versus standard care or placebo (**Q**) (**Level I** [Cochrane Review]); Caesarean section rates are unchanged (**R**) (**Level I** [Cochrane Review]).
2. For oocyte retrieval, electroacupuncture plus sedation reduced procedural and postoperative pain compared with sedation plus placebo or sedation alone (**U**), but may be inferior to paracervical block plus sedation (**Q**) (**Level I** [Cochrane Review]).
3. Acupuncture or acupressure may be effective in the treatment of primary dysmenorrhoea (**S**) (**Level I** [Cochrane Review]).
4. Acupuncture may reduce the frequency of tension-type headaches and migraine (**U**) (**Level I** [Cochrane Review]); in migraine, it may be better tolerated than pharmacological prophylaxis (**N**) (**Level I** [Cochrane Review]).
5. Acupuncture may be effective in a variety of acute pain conditions in the emergency department setting (**S**) (**Level I** [PRISMA]) including back pain (**N**) (**Level I** [PRISMA])
6. Acupuncture by a variety of techniques may reduce postoperative pain and opioid consumption for a variety of surgical types (**S**) (**Level I**); specifically, the benefit may occur after lumbar spinal surgery (**U**) (**Level I** [PRISMA]), total knee arthroplasty (**U**) (**Level I** [PRISMA]), total hip arthroplasty (**N**) (**Level I**) and craniotomy (**N**) (**Level I** [PRISMA]).
7. There is no difference between distant acupuncture and acupuncture at the incisional site for open abdominal surgery (**S**) (**Level I** [PRISMA]).
8. Acupuncture may reduce post-stroke pain (**N**) (**Level I** [PRISMA]).

Photobiomodulation

1. Photobiomodulation may be effective for both prophylaxis and treatment of mucositis in oncology patients (**S**) (**Level I** [PRISMA]).
2. Photobiomodulation may reduce pain after 3rd molar extraction (**N**) (**Level I** [PRISMA]).
3. Needle related pain after arteriovenous fistula access may be reduced by photobiomodulation (**N**) (**Level I**)
4. After episiotomy, photobiomodulation may not reduce pain (**N**) (**Level II**).

☑ Photobiomodulation may have a role in acute postsurgical pain management, however evidence is currently insufficient to make any furrher recommendations (**N**).

Physical therapies

Exercise therapy

1. Following total knee arthroplasty, an exercise intervention in addition to standard post-operative interventions for 8 weeks after discharge may reduce pain and improve function (**N**) (**Level I**).
2. In primary dysmenorrhoea, exercise may reduce acute pain intensity and pain duration (**N**) (**Level I**).

3. Use of a birth ball may improve labour pain (**N**) (**Level I**).

☑ Clear recommendations on the components of exercise interventions (including time point of application, frequency, mode, dose and duration) for acute postoperative pain management cannot be made; different surgical procedures may require different exercise-based interventions (**N**).

☑ Immediate post-operative weight bearing post anterior cruciate ligament reconstruction may reduce pain and does not appear to result in increased joint laxity (**N**).

Prehabilitation

1. Prior to total hip arthroplasty, prehabilitation may reduce postoperative hip pain at 3 months (**N**) (**Level I** [PRISMA]).

☑ A recommendation for the specific type of prehabilitation and dosing parameters cannot be made at this time (**N**).

Rehabilitation

1. Early comprehensive active physiotherapy in the first 4 weeks post spinal surgery may reduce pain and does not appear to increase adverse events (**N**) (**Level I** [PRISMA]).
2. Movement representation interventions (mirror therapy/motor imagery) may reduce acute pain after trauma and surgery (**N**) (**Level I** [PRISMA]).

☑ Accelerated rehabilitation, started within 24 hours post total knee arthroplasty, may reduce pain at the time of discharge (**N**).

Manual and massage therapies

1. Single and multiple doses of massage in the early postoperative period may reduce pain after surgical procedures, including cardiac surgery (**N**) (**Level I [**PRISMA])
2. Massage may decrease pain in the first stage of labour pain compared to standard care (**N**) (**Level I** [Cochrane Review])

☑ The role of manipulative therapy in primary dysmenorrhea is currently unclear (**N**).

Warming and cooling interventions

1. Heat packs may reduce labour pain during the first and second stages (**N**) (**Level I** [Cochrane Review]).
2. Vapocoolants may reduce the pain of intravenous cannulation in adults but its application is associated with discomfort (**N**) (**Level I** [Cochrane Review]).
3. Cryotherapy may reduce pain after total knee arthroplasty but is not superior to compression (**N**) (**Level I** [PRISMA]).
4. Compression cryotherapy may reduce acute pain and analgesia requirements post anterior cruciate ligament reconstruction and pain on day one to three post knee surgery (**N**) (**Level I** [PRISMA]).
5. Intraoperative cryotherapy may reduce post-tonsillectomy pain (**N**) (**Level I** [PRISMA]).
6. Hilotherapy (the application of cold compression at a regulated temperature through a face mask) may reduce pain and swelling after facial skeletal surgery vs cold compression (**N**) (**Level I** [PRISMA]).

8.0 | Specific clinical situations

Postoperative pain

Multimodal postoperative pain management

1. Multimodal analgesia compared to mainly opioid-based analgesia improves pain control and reduces opioid consumption ("opioid-sparing") and adverse effects (**S**) (**Level I** [NMA]).

☑ The concept of multimodal (or "balanced") analgesia suggests the use of combinations of analgesics with different mode or site of action (**S**).

Procedure-specific postoperative pain management

1. An analgesic may have different efficacy in different surgical settings (**U**) (**Level I**).
2. Different surgical procedures cause different pain states (eg musculoskeletal vs visceral) of different severity in different locations, thereby requiring a procedure-specific approach (**S**) (**Level III-2**).

☑ Pooling of data from different postoperative pain states may ignore the specific effects of a specific analgesic in a specific postoperative pain state (**U**).

Acute rehabilitation after surgery, "fast-track" surgery and enhanced recovery after surgery (ERAS)

1. Adherence to multimodal enhanced recovery protocols after surgery protocols reduces hospital length of stay, complication rates (**S**) (**Level I**), postoperative pain severity and opioid requirements (**N**) (**Level III-2 SR**)**.**

☑ Provision of appropriate analgesia is only one of several elements of enhanced recovery after surgery protocols (**S**).

☑ Analgesic techniques, which permit early mobilisation and early enteral feeding, in particular those that are opioid-sparing, may contribute to early recovery after surgery protocols (**S**).

Risks of acute postoperative neuropathic pain

1. Positive screening for acute postoperative neuropathic pain is a risk factor for positive screening of chronic postsurgical neuropathic pain (**N**) (**Level III-2**).
2. Acute neuropathic pain occurs after trauma and surgery (**S**) (**Level IV**).

☑ Treatment of acute neuropathic pain should follow guidelines for chronic neuropathic pain; ketamine, opioids (including tramadol and tapentadol in particular) and alpha-2-delta ligands may offer faster onset of effect than other treatment options (**U**).

Acute postamputation pain syndromes

1. Morphine, gabapentin, ketamine and dextromethorphan reduce phantom limb pain compared to placebo (**U**) (**Level I** [Cochrane Review]).
2. Calcitonin reduces phantom limb pain in the acute (<7 days post amputation) but not the chronic setting (**U**) (**Level I** [Cochrane Review]).
3. Continuous regional block via nerve sheath catheters provides postoperative analgesia after amputation but has no preventive effect on phantom limb pain (**U**) (**Level I**).

4. Treatments aiming at cortical reorganisation such as mirror therapy (**W**) (**Level IV SR**), sensory discrimination training and motor imagery may reduce chronic phantom limb pain (**W**) (**Level III-2 SR**).
5. Perioperative epidural analgesia reduces the incidence of severe phantom limb pain (**U**) (**Level III-2 SR**).
6. Anxiety may be a predictor of phantom limb pain (**N**) (**Level IV**).

☑ Perioperative ketamine may prevent severe phantom limb pain (**U**).

Other postoperative pain syndromes

1. Following thoracotomy, epidural analgesia reduces the incidence of chronic postsurgical pain (**S**) (**Level I** [Cochrane Review]).
2. Following breast cancer surgery, paravertebral block (**S**) (**Level I** [Cochrane Review]) and lidocaine IV infusions reduce the incidence of chronic postsurgical pain (**N**) (**Level I** PRISMA]).
3. Cryoanalgesia of the intercostal nerves at the time of thoracotomy results in no improvement in acute pain, but an increase in chronic pain (**U**) (**Level I**).
4. Video-assisted thoracoscopic surgery versus open thoracic surgery resulted in a reduced rate of chronic post-thoracotomy pain (**N**) (**Level III-3**).
5. Post-thoracotomy, post-mastectomy, post-herniotomy and post-hysterectomy pain syndromes occur frequently (**S**) (**Level IV**) and psychological factors (eg anxiety, catastrophising), chronic preoperative pain and severe acute postoperative pain are consistently reported risk factors for these pain syndromes (**N**) (**Level IV**).

Ambulatory or short-stay surgery

1. Wound infiltration and intraperitoneal instillation with local anaesthetics for short-stay laparoscopic cholecystectomy has good analgesic efficacy, in particular when combined and administered prior to trocar insertion and at commencement of pneumoperitoneum respectively (**S**) (**Level I** [Cochrane Review]).
2. Intraperitoneal instillation with local anaesthetic provides good analgesia for up to 6 hours after short-stay gynaecological laparoscopy (**U**) (**Level I**) and reduces shoulder tip pain for 24 h (**N**) (**Level I** [Cochrane Review]).
3. Ketamine added to caudal local anaesthetic for paediatric day-stay surgery prolongs analgesia, but not motor block (**U**) (**Level I** [PRISMA]); however, concerns regarding neurotoxicity remain.
4. Continuous peripheral nerve blocks after short-stay surgery provide extended analgesia for at least 24 h, leading to reduced opioid requirements (**S**) (**Level I** [PRISMA]), earlier achievement of discharge criteria, less sleep disturbance and improved early rehabilitation (**S**) (**Level II**).
5. Paravertebral block improves pain-related outcomes after short-stay hernia repair (**S**) (**Level I** [PRISMA]) and major breast surgery (**U**) (**Level II**).
6. After ambulatory anterior cruciate ligament repair, analgesia is superior with local infiltration anaesthesia versus femoral nerve blocks and adductor canal blocks; multimodal systemic analgesia, early mobilisation and cooling/compression are also supported (**N**) (**Level I** [PRISMA]).

7. After ambulatory shoulder arthroscopy, interscalene nerve block is superior to other peripheral nerve blocks; adjuvants to increase block duration and systemic multimodal analgesia are also supported (**N**) (**Level I** [PRISMA]).
8. Gynaecological paracervical block provides superior analgesia to intracervical and transcervical block and topical local anaesthetic administration (the latter both without analgesic effect) for ambulatory hysteroscopy (**N**) (**Level I**).
9. Dexamethasone added to local anaesthetics in peripheral nerve blocks and for caudal analgesia or given systemically prolongs duration of analgesia after short-stay surgery (**S**) (**Level I**).
10. Single injection peripheral nerve blocks with long-acting local anaesthetics provide long-lasting postoperative analgesia after short-stay surgery (**S**) (**Level II**).
11. Infiltration of the wound with local anaesthetic provides effective and long-lasting analgesia after many short-stay procedures (**U**) (**Level II**).
12. In the short-stay surgery setting, anti-inflammatories (nonselective NSAIDs, coxibs and dexamethasone) and paracetamol contribute to reduced pain and improved recovery (**U**) (**Level II**).
13. Buprenorphine or dexmedetomidine added to local anaesthetics for peripheral nerve blocks prolong duration of analgesia after short-stay surgery (**U**) (**Level II**).
14. Anterior cruciate ligament repair performed as a short-stay procedure in comparison to an inpatient setting achieves comparable quality of pain relief and better outcomes (**N**) (**Level III-3 SR**).
15. Pain relief after short-stay surgery remains poor (**U**) (**Level IV**) and is a common cause of unplanned re-presentation (**U**) (**Level III-3**).
16. Continuous peripheral nerve blocks have been shown to be safe at home after short stay surgery, if adequate resources and patient education are provided (**U**) (**Level IV**).
17. Predictive factors of severe pain after short-stay surgery are preoperative pain, high expectation of postoperative pain, younger age and certain types of surgery (in particular orthopaedic surgery) (**N**) (**Level IV**).

☑ Preoperative patient-centered education (verbal and written) and telephone follow-ups may improve anxiety, pain and functional outcomes and patient satisfaction after ambulatory surgery (**N**).

Cranial neurosurgery

1. Local anaesthetic infiltration of the scalp provides early analgesia after craniotomy and reduces opioid requirements (**S**) (**Level I** [PRISMA]).
2. Intraoperative dexmedetomidine provides early analgesia after craniotomy and reduces opioid requirements compared to placebo or remifentanil (**S**) (**Level I** [PRISMA]).
3. Morphine is more effective than codeine and tramadol for pain relief after craniotomy (**U**) (**Level II**).
4. Craniotomy leads to significant pain in the early postoperative period (**U**) (**Level IV**), which is however not as severe as pain from other surgical interventions (**U**) (**Level III-2**).
5. Craniotomy can lead to significant chronic headache (**U**) (**Level IV**).

☑ Acute pain following craniotomy is underestimated and often poorly treated (**U**).

Spinal surgery

1. Epidural analgesia compared to systemic analgesia after spinal surgery in children improves pain up to 72 hours postoperatively (**N**) (**Level I**[Cochrane Review]).
2. Perioperative use of gabapentin or pregabalin improves analgesia and reduces opioid requirements after spinal surgery (**S**) (**Level I** [PRISMA]).
3. NSAIDs provide analgesic benefits as well as opioid-sparing effects after spinal surgery (**S**) (**Level I** [PRISMA]).
4. Intravenous dexmedetomidine improves early postoperative analgesia and reduces analgesic requirement up to 48 hours after spinal surgery (**N**) (**Level I** [PRISMA]).
5. Intravenous corticosteroids improve analgesia and reduce nausea and length of stay after spinal surgery (**N**) (**Level I** [PRISMA]).
6. Epidural steroid application intraoperatively by the surgeon provides analgesic benefit up to 24 hours and reduces length of stay after spinal surgery(**N**) (**Level I** [PRISMA]).
7. Perioperative pregabalin improves functional outcome after laminectomy at 3 months (**U**) (**Level II**).
8. Local infiltration anaesthesia improves analgesia and reduces opioid requirements after spinal surgery; this benefit is enhanced with preincision infiltration compared to infiltration at wound closure (**U**) (**Level II**).
9. Perioperative systemic lidocaine infusion improves analgesia and reduces opioid requirements after spinal surgery (**W**) (**Level II**).
10. NSAID use for less than 14 days does not increase the risk of nonunion after spinal fusion, except with high-dose ketorolac (**U**) (**Level III-3**).

☑ Acute pain management following spinal surgery is often complicated by preoperative chronic pain and long term medication use (**U**).

Acute pain following spinal cord injury

1. Alpha-2-delta ligands (gabapentin/pregabalin) are effective in the treatment of neuropathic pain following spinal cord injury (**S**) (**Level I**).
2. Antidepressants (amitriptyline, duloxetine and venlafaxine) are effective in the treatment of neuropathic pain following spinal cord injury but only in those with co-morbid depression (**N**) (**Level I**).
3. Intravenous opioids, ketamine ((**U**) (**Level I**), lidocaine and tramadol are effective in the treatment of neuropathic pain following spinal cord injury (**U**) (**Level II**).

☑ Treatment of acute spinal cord injury pain is largely based on evidence from studies of other neuropathic and nociceptive pain syndromes (**U**).

☑ There is currently insufficient evidence to support non-pharmacological treatments (TENS, acupuncture, self-hypnosis or cognitive behavioural therapy) for spinal cord injury pain (**N**).

Chest trauma (Rib fractures)

1. Surgical fixation in patients with 3 or more fractured ribs improves outcome with regard to incidence of pneumonia and need for tracheostomy (**N**) (**Level I** [Cochrane Review]), duration of ventilation, ICU and hospital stay (**N**) (**Level I**) and mortality (**N**) (**Level III-2 SR**).
2. Continuous thoracic epidural analgesia and continuous intercostal and paravertebral blocks provide similar analgesia and are superior to intravenous opioids for rib fracture related pain (**N**) (**Level I** [PRISMA]).
3. Systemic NSAIDs and ketamine are efficacious analgesic adjuvants for rib fracture related pain (**N**) (**Level III-3**)

☑ Emerging regional techniques such as serratus anterior and erector spinae plane blocks (single shot and continuous infusion) are supported by case series and could be considered for rib fracture analgesic management (**N**).

☑ Chest trauma with rib fractures carries a high risk of potentially life-threatening complications; excellent analgesia and aggressive physical rehabilitation, ideally provided in a protocolised clinical pathway, can improve outcome (**N**)

Acute pain after hip (neck of femur) fractures

1. Lower limb nerve blocks with local anaesthetics reduce pain, analgesia requirements and lengthen time to rescue analgesia in hip fracture patients compared to systemic analgesia; there is no advantage of a specific nerve block, insertion technique or continuous versus single injection administration (**S**) (**Level I** [Cochrane Review]).
2. Lower limb nerve blocks decrease the risk of pneumonia in hip fracture patients, but do not decrease the risk of delirium, myocardial infarction/ischaemia or mortality (**N**) (**Level I** [Cochrane Review]).
3. Morphine should be avoided due to increased risk of delirium in hip fracture patients, who have a high prevalence of renal impairment (**N**) (**Level III-3 SR**).
4. Arthroplasty techniques in hip fracture patients are associated with less pain and opioid requirements than non-arthroplasty techniques (**N**) (**Level III-2**).

☑ Integrated orthogeriatric care, utilisation of care bundles and adherence to clinical care standards improve outcomes in hip fracture patients (**N**).

Acute burns injury pain

1. The use of biosynthetic dressings is associated with a decrease in time to healing and a reduction in pain during burns dressings changes (**U**) (**Level I** [Cochrane Review]).
2. Virtual reality distraction, augmented reality techniques and multimodal distraction methods reduce pain and unpleasantness during burns dressings (**S**) (**Level I** [PRISMA]).
3. Music interventions are helpful in reducing pain, anxiety and heart rate in burns patients (**N**) (**Level I** [PRISMA])
4. Opioids, particularly via PCA, are effective in burns pain, including procedural pain (**U**) (**Level II**).

5. Pregabalin reduces pain following acute burns injury (**U**) (**Level II**).
6. Sedation and anxiolysis with lorazepam improves procedural pain relief in acute burns injury (**U**) (**Level II**).
7. Regional analgesia reduces donor site pain in selected burns patients (**U**) (**Level II**).
8. Gabapentin reduces pain and opioid consumption following acute burns injury (**U**) (**Level III-3**).
9. PCA with ketamine and midazolam mixture provides effective analgesia and sedation for burns dressings (**U**) (**Level IV**).

☑ Acute pain following burns injury can be nociceptive and/or neuropathic in nature and may be constant (background pain), intermittent or procedure-related (**U**).

☑ Acute pain following burns injury requires aggressive multimodal and multidisciplinary treatment and may benefit from protocolised management approaches (**S**). This is particularly important as severely burn injured patients require repeated procedures and frequently have persistent issues of chronic pain, pruritus, post-traumatic stress and other psychological consequences.

☑ Pruritus is a common symptom following burns injury and alpha-2-delta ligands are useful in its management (**N**).

Acute medical pain

Acute abdominal pain

1. Provision of analgesia does not interfere with the diagnostic process in acute abdominal pain and does not increase the risk of errors in clinical management (**U**) (**Level I** [Cochrane Review]).
2. NSAIDs, opioids and intravenous metamizole (dipyrone) provide effective analgesia for renal colic (**S**) (**Level I** [Cochrane Review]).
3. NSAIDs given for renal colic reduce pain (**N**) (**Level I** [PRISMA]) and rescue analgesia requirements with less vomiting compared with opioids, particularly pethidine (meperidine) (**S**) (**Level I** [Cochrane Review]).
4. Alpha blockers as expulsive therapy for ureteral stones reduce the number of pain episodes and analgesic requirements (**S**) (**Level I** [Cochrane Review]).
5. Antispasmodics and tricyclic antidepressants, but not bulking agents, are effective for the treatment of acute pain in irritable bowel syndrome (**S**) (**Level I** [Cochrane Review]) as well as psychological interventions (**N**) (**Level I**).
6. NSAIDs are effective in primary dysmenorrhoea and superior to paracetamol (**S**) (**Level I** [Cochrane Review]).
7. The smooth muscle relaxant buscopan does not add further analgesic benefit when combined with metamizole (dipyrone) (**U**) (**Level I** [Cochrane Review]), opioids or NSAIDS to treat pain of renal colic (**U**) (**Level II**).
8. High-frequency TENS, possibly some dietary supplements and acupuncture/acupressure are effective in the treatment of primary dysmenorrhoea (**S**) (**Level I** [Cochrane Review]).

9. NSAIDS are superior to placebo and spasmolytics and as effective as opioids in the treatment of biliary colic (**S**) (**Level I** [Cochrane Review])
10. The perioperative use of NSAIDs for endoscopic retrograde cholangiopancreatography (ERCP) reduces the risk of post ERCP pancreatitis (**S**) (**Level I** [PRISMA]).
11. $5HT_3$ antagonists reduce some of the symptoms of irritable bowel syndrome (**S**) (**Level I** [QUOROM).
12. The onset of analgesia is faster when NSAIDs are given intravenously for the treatment of renal colic (**U**) (**Level I**).
13. Intravenous paracetamol is as effective as intravenous morphine and superior to intramuscular piroxicam for analgesia in renal colic (**U**) (**Level II**).
14. There is no difference between pethidine and morphine for analgesia in renal colic (**U**) (**Level II**).
15. Low-dose ketamine is an effective analgesic for renal colic pain (**N**) (**Level II**).
16. IV lidocaine is an effective analgesic for renal colic pain (**N**) (**Level IV SR**).

Herpes zoster-associated pain

1. Antiviral agents started within 72 hours of onset of the herpes zoster rash accelerate the resolution of acute pain (**U**) (**Level I**) but do not reduce the incidence, severity and duration of postherpetic neuralgia (**U**) (**Level I** [Cochrane Review]).
2. Immunisation of persons aged 60 years or older reduces the incidence of herpes zoster and thereby postherpetic neuralgia with Zostavax® (**U**) (**Level I** [Cochrane Review]) and Shingrix® (**N**) (**Level II**).
3. Continuous or repeated paravertebral blocks in the acute phase of herpes zoster reduce the incidence of postherpetic neuralgia at 3, 6 and 12 months (**N**) (**Level I**).
4. Amitriptyline (used in low doses for 90 days from onset of the herpes zoster rash) reduces the incidence of postherpetic neuralgia (**U**) (**Level II**).
5. Topical aspirin, topical lignocaine patch or controlled-release oxycodone provide analgesia in acute pain due to herpes zoster (**U**) (**Level II**).
6. Nerve blocks in the acute phase of herpes zoster reduce the duration of herpes zoster-associated pain (**N**) (**Level III-I SR**).
6. Continuous epidural analgesia in the acute phase of herpes zoster reduces the incidence of postherpetic neuralgia at 3 months (**N**) (**Level III-I SR**).

☑ Provision of early and appropriate analgesia is an important component of the management of herpes zoster and may have benefits in reducing the incidence of postherpetic neuralgia (**U**).

Acute cardiac pain

1. The routine use of oxygen in normoxic patients with acute myocardial infarction does not reduce pain or mortality (**S**) (**Level I** [Cochrane].
2. Morphine is an effective and appropriate analgesic for acute cardiac pain, but may interfere with pharmacokinetics and pharmacodynamics of some platelet inhibitors (**Q**) (**Level II**).

3. Nitroglycerine is an effective and appropriate agent in the treatment of acute ischaemic chest pain (**S**) (**Level IV**).

☑ The mainstay of analgesia in acute coronary syndrome is the restoration of adequate myocardial oxygenation, nitroglycerine, beta blockers and strategies to improve coronary vascular perfusion (**U**).

Acute pain associated with haematological disorders

1. Parenteral corticosteroids reduce the duration of severe pain, analgesia requirements and hospital length of stay, without major adverse effects, during vaso-occlusive crises in sickle cell disease (**U**) (**Level I** [Cochrane Review]).
2. There is no evidence that fluid replacement therapy (**S**) or intravenous or oral magnesium reduces pain associated with vaso-occlusive crises in sickle cell disease (**N**) (**Level I** [Cochrane Review]).
3. Hydroxyurea decreases the frequency of vaso-occlusive crises, life-threatening complications and transfusion requirements in sickle cell disease (**S**) (**Level I** [Cochrane Review]).
4. Zinc reduces the incidence of painful vaso-occlusive crises in sickle cell disease (**U**) (**Level I** [Cochrane Review]).
5. Intravenous opioid loading optimises analgesia in the early stages of a vaso-occlusive crisis in sickle cell disease; effective analgesia may be continued with intravenous opioid therapy, optimally as PCA, or as oral opioids (**S**) (**Level II**).
6. Single-dose ketorolac does not reduce opioid requirements in vaso-occlusive crisis in sickle cell disease (**N**) (**Level II**), but may increase the risk of acute kidney injury (**N**) (**Level III-3**).
7. Oxygen supplementation does not decrease pain during a vaso-occlusive crisis in sickle cell disease (**U**) (**Level II**), but hyperbaric oxygen may be effective (**U**) (**Level III-3**).
8. Intravenous ketamine and intravenous lidocaine reduced pain intensity and opioid requirements in vaso-occlusive crisis in sickle cell disease (**N**) (**Level IV**).

Acute headache

Tension-type headache

1. Acupuncture may be effective in the treatment of tension-type headache (**S**) (**Level I** [Cochrane Review]).
2. Simple analgesics such as paracetamol or NSAIDs, either alone or combined, are effective in the treatment of episodic tension-type headache (**S**) (**Level I** [PRISMA]).
3. Metoclopramide, metamizole and chlorpromazine as parenteral treatments of tension-type headache have high efficacy (**U**) (**Level I** [PRISMA]).
4. The combination of caffeine/aspirin/paracetamol is superior to paracetamol in the treatment of episodic tension-type headache (**U**) (**Level I**).

Migraine

5. Paracetamol is effective in the treatment of migraine, however less than other analgesics; the efficacy is increased when combined with metoclopramide (**U**) (**Level I** [Cochrane Review]).

6. Aspirin, ibuprofen, diclofenac and dipyrone are effective in the treatment of migraine; soluble preparations of ibuprofen provide a faster onset (**U**) (**Level I** [Cochrane Review]).
7. For sumatriptan, subcutaneous administration achieves the fastest onset of effect and highest efficacy (**U**) (**Level I** [Cochrane Review]).
8. The combination naproxen/sumatriptan has increased efficacy and better tolerability than sumatriptan on its own (**N**) (**Level I** [Cochrane Review]).
9. The addition of caffeine to simple analgesics improves their analgesic efficacy and tolerability in acute migraine (**N**) (**Level I** [Cochrane Review]).
10. Hyperbaric oxygen therapy is effective in controlling pain in migraine, but no other symptoms and outcomes (**U**) (**Level I** [Cochrane Review]).
11. A significant placebo effect occurs in migraine treatment (**N**) (**Level I** [QUOROM]), leading to an underestimation of treatment effects of analgesic medications (**N**) (**Level II**).
12. Parenteral antiemetics, metoclopramide (**S**) (**Level I** [PRISMA]) and droperidol (**U**) (**Level I**) are effective in the treatment of migraine.
13. Phenothiazines and butyrophenones (at the expense of more adverse effects) are effective in the treatment of migraine, in particular in the emergency department (**S**) (**Level I**).
14. All triptans are more effective than placebo in the treatment of severe migraine (**S**) (**Level I**), however 30 to 40% of patients may not respond (**N**) (**Level I**).
15. Triptans and mefenamic acid are effective in treatment of menstruation-related migraine (**U**) (**Level I**).
16. Some opioids are more effective than placebo in the treatment of acute migraine (**U**) (**Level I**), but their use in this setting is associated with significant adverse effects and poor outcomes (**S**) (**Level III-2**).
17. Pethidine is less effective than most other migraine treatments and should not be used (**U**) (**Level I**).
18. Intravenous magnesium may have some analgesic effect compared to placebo in migraine (**Q**) (**Level I** [PRISMA]).
19. A "*stratified care strategy*" is effective in treating migraine (**U**) (**Level II**).
20. Ergotamine derivatives, but not triptans, increase the rate of severe myocardial ischaemic events (**U**) (**Level III-2 SR**).
21. Migraine in pregnancy is a risk factor for gestational hypertension, preeclampsia and cardiovascular complications (**U**) (**Level III-2**).

Cluster headache

22. Parenteral triptans (sumatriptan or zolmitriptan) or high-flow oxygen therapy are effective treatments for cluster headache attacks (**S**) (**Level I** [Cochrane Review]).
23. Sphenopalatine ganglion local anaesthetic block has moderate evidence support for the treatment of acute cluster headaches (**N**) (**Level IV SR**).

Postdural puncture headache

24. There is no evidence that bed rest or fluid supplementation are beneficial in the treatment and prevention of postdural puncture headache (**S**) (**Level I** [Cochrane Review]).

25. Epidural blood patch administration is more effective than conservative treatment or a sham procedure in the treatment of postdural puncture headache (**S**) (**Level I** [Cochrane Review]).

26. Risk of postdural puncture headache is reduced with preventive use of morphine, cosyntropin or aminophylline, especially in patients at high risk; preventive dexamethasone use increases risk of postdural puncture headache (**N**) (**Level I** [Cochrane Review]).

27. Caffeine, gabapentin, hydrocortisone or theophylline are effective treatments for postdural puncture headache (**S**) (**Level I** [Cochrane Review]).

28. The incidence of postdural puncture headache is reduced by using smaller-gauge spinal or non-cutting bevel needles or by orientating the cutting bevel parallel to the spinal sagittal plane (**U**) (**Level I**).

Medication overuse headache

29. Frequent use (>8–10 days/month) of paracetamol, NSAIDs and opioids for recurrent acute headache (more so than triptans and ergot derivatives) may lead to medication overuse headache; weaning and use of preventive medication are recommended management approaches (**S**) (**Level IV SR**).

☑ Opioids should be used with extreme caution in the treatment of headache; pethidine should not be used at all (**S**).

Acute pain associated with neurological disorders

1. Various anticonvulsants (**U**) (**Level I** [PRISMA]) and duloxetine (**N**) (**Level II**) have beneficial effects in the treatment of neuropathic pain associated with multiple sclerosis

2. Cannabinoids have a clinically small effect on spasticity caused by multiple sclerosis (**U**) (**Level I**); the effect on neuropathic pain associated with multiple sclerosis is unclear and may depend on the preparation used (**W**) (**Level I** [PRISMA]).

3. With cannabinoid use in multiple sclerosis, there is a high rate of minor adverse effects and serious adverse psychopathological effects occur in nearly 1% of patients (**U**) (**Level I**).

4. Acupuncture (**N**) (**Level I**), non-invasive brain stimulation (**N**) (**Level III-3 SR**) and motor cortex stimulation (**N**) (**Level IV SR**) may reduce post-stroke pain.

5. Local anaesthetics (mainly lidocaine) by local and systemic administration, anticonvulsants (phenytoin or IV fosphenytoin) and sumatriptan reduce pain in acute exacerbations of trigeminal neuralgia (**N**) (**Level IV SR**).

6. Motor cortex stimulation may reduce acute pain in trigeminal neuralgia (**N**) (**Level IV SR**)

7. Deep brain stimulation may improve pain relief in Parkinson's disease (**N**) (**Level IV**).

☑ Treatment of acute pain associated with neurological disorders is based largely on evidence from trials for the treatment of a variety of chronic neuropathic pain states (**S**).

Acute orofacial pain

Acute dental pain

1. NSAIDs and emergency pulpectomy reduce pain in patients with acute apical periodontitis (**U**) (**Level I**) with insufficient evidence to support analgesic benefit from adding antibiotics (**S**) (**Level I** [Cochrane Review]).

Dental extraction

2. Paracetamol, nonselective NSAIDs and coxibs provide safe and effective analgesia with minimal adverse effects after dental extraction (**S**) (**Level I** [Cochrane Review]).
3. Combinations of paracetamol with ibuprofen (**U**) (**Level I** [Cochrane Review]) and other nonselective NSAIDs (**U**) (**Level I**) provide superior analgesia to either drug alone after dental extraction.
4. Tramadol provides equal analgesia to paracetamol/weak opioid and aspirin/weak opioid combinations (**U**) (**Level I** [Cochrane Review]) and tramadol/paracetamol combinations provide superior analgesia to tramadol alone after dental extraction (**U**) (**Level I**).
5. Nonselective NSAIDs and coxibs provide similar analgesia, which is superior to paracetamol, codeine, combinations of paracetamol/codeine (**U**) (**Level I**), tramadol (**S**) (**Level I**) and pethidine (**U**) (**Level II**) after dental extraction.
6. Perioperative corticosteroid administration reduces swelling, but not pain (**U**) (**Level I**), and reduces postoperative nausea (**U**) (**Level II**) after third molar extraction.

Tonsillectomy

7. Nonselective NSAIDs (**U**) (**Level I**), in particular aspirin and ketorolac (**U**) (**Level II**), increase the risk of reoperation for bleeding after tonsillectomy in adults, but not in children (**U**) (**Level I** [Cochrane Review]).
8. Intraoperative dexamethasone administration reduces postoperative pain, nausea and vomiting and time to resumption of oral intake after tonsillectomy (**S**) (**Level I** [Cochrane Review]), with no increase in adverse effects (**U**) (**Level I** [Cochrane Review]).
9. Paracetamol, NSAIDs (**S**) (**Level I** [PRISMA]), dexamethasone, preoperative alpha-2-delta ligands (**S**) and dextromethorphan are effective analgesics after tonsillectomy (**N**) (**Level I** [PRISMA]).
10. Intraoperative cryothgerapy may reduce post-tonsillectomy pain (**N**) (**Level I** [PRISMA]).
11. Oral administration of honey versus control reduces postoperative pain and analgesic use after tonsillectomy (**N**) (**Level I** [PRISMA]).
12. Peritonsillar infiltration or topical application of local anaesthetics are equally effective in producing a modest reduction in acute post-tonsillectomy pain (**U**) (**Level I**).
13. Dexamethasone, magnesium (and with limited support pethidine and tramadol) combined with local anaesthetics for peritonsillar infiltration improve analgesia and other outcomes after tonsillectomy (**N**) (**Level I**).
14. Perioperative antibiotics show no benefit in post-tonsillectomy pain, but increase adverse effects (**S**) (**Level I**).
15. Acupuncture may reduce post-tonsillectomy pain compared to control group or sham acupuncture (**N**) (**Level I**)

16. Peritonsillar infiltration with tramadol or ketamine may reduce post-tonsillectomy pain and analgesia requirements but was no more effective than equivalent doses administered parenterally (**U**) (**Level II**).

Pharyngitis

17. Corticosteroids (**S**) (**Level I** [Cochrane Review]) and antibiotics (**U**) (**Level I** [Cochrane Review]) improve analgesia and reduce duration of pain in pharyngitis.

18. Amylmetacresol/2,4-dichlorobenzylalcohol (AMC/DCBA) lozenges (**N**) (**Level I** [PRISMA]), ketamine gargle (**N**) (**Level I** [PRISMA]), benzydamine spray (**U**) (**Level I**) and other topical analgesics (**U**) (**Level II**) provide analgesia superior to placebo in acute sore throat with minimal adverse effects.

19. Corticosteroids reduce acute pain associated with peritonsillar abscess (following drainage and antibiotics) (**S**) (**Level I** [PRISMA]).

20. Paracetamol, NSAIDs (nonselective NSAIDs or coxibs) and opioids, administered as monotherapy or in combination, are effective analgesics in acute pharyngitis (**U**) (**Level I**).

Sinusitis and otitis media

21. Oral corticosteroids have no analgesic effect in sinusitis (**U**) (**Level I** [Cochrane Review]), but intranasal corticosteroids reduce facial pain and improve recovery (**S**) (**Level I** [Cochrane Review]).

22. Antibiotic treatment of acute otitis media vs placebo or control has no effect on acute pain, only limited effect on later pain, but increases the risk of adverse effects (**N**) (**Level I** [Cochrane Review]).

23. In acute otitis media, topical local anaesthetic drops are effective in children compared to placebo and equivalent to naturopathic drops (**S**) (**Level I** [Cochrane Review]).

☑ Codeine should not be used in children, especially after adenoidectomy or tonsillectomy, due to an increased risk of opioid-induced ventilatory impairment and death (**U**).

☑ Recurrent or persistent orofacial pain requires biopsychosocial assessment and appropriate multidisciplinary approaches (**U**).

☑ Neuropathic orofacial pain, which is often post-traumatic (iatrogenic), may be exacerbated by repeated dental procedures, incorrect drug therapy or psychosocial factors (**U**).

Acute pain in patients with HIV infection

1. High-concentration capsaicin patches have some efficacy in treating neuropathic pain in patients with HIV/AIDS (**S**) (**Level I** [Cochrane Review]).
2. Smoking cannabis has short-term efficacy in treating neuropathic pain in patients with HIV/AIDS, although potential study bias means that this is not recommended as routine treatment (**Q**) (**Level I** [PRISMA])**.**
3. HIV/AIDS patients with a history of problematic drug use report higher opioid analgesic use but also more intense pain (**U**) (**Level III-2**).
4. Pain, and notably neuropathic pain, is common in patients with HIV (**U**) (**Level IV**).

☑ HIV/AIDS has become a chronic, manageable condition; in view of limited specific evidence, the treatment of pain in patients with HIV/AIDS should be based on similar principles to those for the management of acute, cancer and chronic pain in the general population (**S**).

☑ Interactions between antiretroviral medications, antibiotics and analgesics should be considered in this population and reference to a current guide of likely drug interactions is strongly recommended (**S**).

Acute cancer pain

1. Intranasal, sublingual and buccal fentanyl preparations are effective treatments for breakthrough pain in cancer patients (**U**) (**Level I** [Cochrane Review]) with similar efficacy to intravenous administration (**U**) (**Level I** [PRISMA]) and superior to oral morphine (**U**) (**Level I**).
2. Radiotherapy is an effective treatment of acute cancer pain due to bone metastases (**U**) (**Level I** [Cochrane Review]), while bone-targeting agents (bisphosphonates, denosumab) are beneficial in delaying the onset of bone pain rather than providing analgesia (**W**) (**Level I** [PRISMA]).
3. Neurolytic coeliac plexus block in pancreatic cancer lowers pain intensity and opioid analgesic requirements for at least 8 weeks (**U**) (**Level I** [Cochrane Review]).
4. Opioids, via PCA or a continuous infusion, provide effective analgesia in mucositis; PCA is associated with reduced opioid requirements and pain duration (**U**) (**Level I** [Cochrane Review]).
5. Oral cryotherapy (sucking on ice chips or holding ice water in the mouth before, during, and/or after rapid infusions of systemic therapies that result in mucositis) effectively prevents mucositis (**N**) (**Level I** [Cochrane Review]).
6. Music interventions may be effective in reducing pain intensity in patients with cancer (**N**) (**Level I** [Cochrane Review]).
7. Topical treatment with doxepin (**S**), amitriptyline (**N**), diclofenac (**N**), benzydamine (**N**) (**Level I** [PRISMA]), povidone-iodine (**U**) (**Level I**) and morphine (**S**) (**Level II**) compared to placebo improve pain relief due to mucositis.
8. Low-level laser therapy reduces and when used prophylactically prevents pain and severity of mucositis (**S**) (**Level I** [PRISMA]).
9. Patient education about cancer pain is a key factor in optimising pain management (**U**) (**Level I**).
10. Opioid doses for individual patients with cancer pain should be titrated to achieve maximum analgesic benefit with minimal adverse effects (**U**) (**Level II**).
11. Analgesic medications prescribed for cancer pain should be adjusted to alterations of pain intensity (**U**) (**Level III-2**).
12. Neuropathic pain or mixed nociceptive-neuropathic pain has an estimated frequency of 30-40% in patients with cancer (**S**) (**Level IV SR**).

- ☑ Acute pain in patients with cancer often signals disease progression; sudden severe pain in patients with cancer should be recognised as a medical emergency and immediately assessed and treated (**U**).
- ☑ Prompt assessment and fast coordinated management of spinal metastases with suspected spinal cord compression is required to mitigate against neurological deficit (**U**).
- ☑ Cancer patients receiving controlled-release opioids need access to immediate-release opioids for titration of breakthrough pain; ~~s~~election of breakthrough medication should consider the time course and aetiology of the pain flare (**U**).
- ☑ If nausea and vomiting accompany acute cancer pain, parenteral opioids are needed (**U**).
- ☑ Transdermal opioids are inappropriate to control acute unstable pain (**U**).
- ☑ High interindividual variability in opioid conversion rates dictates that all opioid rotations should be individualised and monitored, particularly where higher opioid doses are in use (**U**).

Acute pain management in intensive care

1. Plasma exchange in acute Guillain-Barre syndrome improves outcome including analgesia (**U**) (**Level I** [Cochrane Review]).
2. Carbamazepine and gabapentin may reduce the pain associated with Guillain-Barre syndrome, based on limited and low-quality evidence (**U**) (**Level I** [Cochrane Review]).
3. Non-opioids including NSAIDs and paracetamol improve analgesia in selected intensive care unit patients (**S**) (**Level I** [PRISMA]).
4. Remifentanil provides no advantages over other opioids in ventilated intensive care unit patients (**U**) (**Level I**).
5. Ketamine decreases cumulative opioid doses in mechanically ventilated patients, with positive effects on haemodynamics and reduced requirements for sedation, but with an increased risk of psychomimetic adverse effects (**N**) (**Level II**).
6. The formal assessment and management of pain and agitation in ventilated intensive care unit patients decreases the incidence of pain, the duration of ventilation, the length of ICU stay and mortality (**U**) (**Level III-1**).
7. Prolonged opioid infusions for >6 days and higher cumulative opioid dose increase the risk of acute withdrawal if the opioid infusion is abruptly ceased (**N**) (**Level III-2**).
8. Procedures such as endotracheal tube suctioning are consistently reported as uncomfortable and painful (**U**) (**Level III-2**).

- ☑ The aetiology of acute pain in critically ill patients is complex and encompasses all domains of the sociopsychobiomedical model of pain (**N**).
- ☑ Observation of behavioural and physiological responses permits assessment of pain in unconscious patients (**U**).
- ☑ Routine monitoring for pain in sedated intensive care patients should be performed, using the Behavioural Pain Scale or the Critical-Care Pain Observation Tool (**U**).
- ☑ Analgesia management should be targeted to the potential aetiologies of acute pain (**N**).

☑ Opioids are the recommended first-line analgesic agents in ventilated intensive care patients (**U**).

☑ The risk of NSAIDs in critically ill patients may be overestimated; NSAIDs may provide effective analgesia as a part of multimodal analgesia (**N**).

☑ Regional analgesia techniques should be considered in patients undergoing large intra-abdominal surgical procedures and trauma (**N**).

☑ Intensive care unit patients should be provided with appropriate analgesia prior to and during potentially painful procedures, in particular as recall of discomfort, pain and procedures can be a source of post-traumatic stress (**S**).

Acute pain management in emergency departments

1. Paracetamol, in particular if administered IV, and NSAIDs are effective primary analgesics for use in the emergency department (**N**) (**Level I** [PRISMA]).
2. Sublingual buprenorphine (**N**) (**Level I** [PRISMA]) or intranasal fentanyl (**N**) (**Level I**) are effective alternatives to parenteral opioids in the emergency department.
3. Low dose ketamine is a safe and effective analgesic alone or when combined with opioids in the emergency department, but increases neuro-psychological adverse events (**N**) (**Level I** [PRISMA]).
4. Appropriate doses of intravenous opioids are effective in treating acute severe pain in the emergency department and ideally should be titrated according to nurse-initiated and patient-driven protocols; there is no preference for a specific opioid (**U**) (**Level I**).

Abdominal pain

5. Provision of analgesia does not interfere with the diagnostic process in acute abdominal pain and does not increase the risk of errors in clinical management (**U**) (**Level I** [Cochrane Review]).

Migraine

6. NSAIDs, triptans (**S**) (**Level I** [Cochrane]), phenothiazines (prochlorperazine, chlorpromazine), butyrophenones and metoclopramide are effective to treat migraine in the emergency department (**U**) (**Level I**).

Fractured neck of femur

7. Lower limb nerve blocks with local anaesthetics reduce pain, analgesia requirements and lengthen time to rescue analgesia in hip fracture patients compared to systemic analgesia; there is no advantage of a specific nerve block, insertion technique or continuous versus single injection administration (**S**) (**Level I** [Cochrane Review]).

Shoulder dislocation

8. Intra-articular local anaesthetics provide comparable analgesia for reduction of gleno-humeral dislocation to procedural sedation and analgesia methods with fewer adverse events (**N**) (**Level I** [Cochrane Review]).

Wounds

9. Buffering of lignocaine with bicarbonate reduces the pain of infiltration, particularly when using lignocaine with adrenaline (**U**) (**Level I** [Cochrane Review]).

10. Topical local anaesthetic agents (including those in liposomal formulations) (**S**) (**Level I** [Cochrane Review]) or topical local anaesthetic-adrenaline agents (**U**) (**Level II**) provide effective analgesia for wound care in the emergency department.

Musculoskeletal Pain

11. Centrally acting muscle relaxants do not improve analgesia in the acute treatment of lower back pain (**N**) (**Level II**).

Non-pharmacological management of pain

12. Acupuncture may provide effective analgesia as a single agent or adjunct in the emergency department (**N**) (**Level I** [PRISMA]).

☑ To ensure optimal management of acute pain, emergency departments should adopt systems to ensure adequate assessment of pain, provision of timely, adequate and appropriate analgesia, frequent monitoring and reassessment of pain (**U**).

Prehospital analgesia

1. Transcutaneous electrical nerve stimulation TENS provides pain relief in the prehospital setting (**N**) (**Level I** [PRISMA]).
2. Intravenous morphine, fentanyl and tramadol are equally effective in the prehospital setting (**S**) (**Level II**).
3. Nitrous oxide is an effective analgesic agent in prehospital situations (**U**) (**Level II**).
4. Methoxyflurane, in low concentrations, is an effective analgesic with rapid onset in the prehospital and hospital setting with good safety data (**U**) (**Level II**).
5. Ketamine is a safe and effective analgesic in the prehospital setting (**U**) (**Level II**).
6. Moderate to severe pain is common in both adult and paediatric patients in the prehospital setting (**S**) (**Level IV**) and is often poorly managed (**N**) (**Level III-2**).
7. Fascia iliaca compartment block is an effective analgesic technique for patients with isolated femoral shaft fractures in the prehospital setting (**N**) (**Level IV SR**).
8. The prehospital setting presents challenges beyond those encountered in hospital to the assessment, documentation, treatment and reassessment of pain in both adult and paediatric patients (**N**) (**Level IV**).

☑ Nonpharmacological measures are effective in providing pain relief and should always be considered and used if practical (**U**).

Discharge opioid medication for acute pain management

1. Short-term opioid therapy may lead to long term opioid use and misuse (**S**) (**Level III-2**); risk factors for prolonged postoperative use include preoperative opioid use, type of surgery, slow-release opioids, psychological and social factors and pre-existing alcohol or substance use disorder (N) (**Level III-2**).
2. Recent introduction of opioid therapy may increase the risk of falls (**S**) (**Level III-2**).
3. Recent introduction of opioid therapy or recent dose escalation may impair driving (**S**) (**Level III-2**), thereby leading to increased driving accidents (**N**) (**Level III-3 SR**); this risk is further increased by combined use of opioids and alcohol (**N**) (**Level III-2**).

4. Many patients who retain unused opioid tablets are willing to share them with others (**S**) (**Level III-2**); this contributes to increased risks of abuse and adverse effects in the recipients (**N**) (**Level IV**).
5. The most common source of prescription opioids for nonmedical use is a friend or relative (**N**) (**Level III-3**).

☑ Unused opioids prescribed for postoperative pain are potentially a large reservoir for opioid abuse, misuse and diversion (**S**).

☑ A "universal precautions" approach for opioid prescribing should be used in the setting of prescribing discharge medications (**S**).

☑ Prescribing discharge medications should be done in consideration of opioid requirements on the day before discharge, avoiding slow-release opioids and for a limited duration (**N**).

☑ Patient education about risks of opioids and safe disposal of unused medication by return to a pharmacy and follow-up by GP or pain medicine services in case of ongoing issues improve safety of discharge medications (**N**).

9.0 | Other specific patient groups

The pregnant patient

Use of analgesic medications in pregnancy

1. Short-term use of NSAIDs in late pregnancy is associated with an increase in the risk of premature closure of the ductus arteriosus (**U**) (**Level I** [Cochrane Review]).
2. The chronic use of opioids during pregnancy may be associated with some teratogenic effects, childhood neurocognitive delay and/or negative neurobehavioural outcomes; however, it is difficult to separate the influence of multiple confounders in this patient group (**Q**) (**Level III-2 SR**).
3. Retrospective epidemiological studies linking paracetamol use in pregnancy to later development of childhood asthma are inherently confounded (**U**); when adjusted for respiratory tract infections in the child the association is lost (**Q**) (**Level III-2 SR**).
4. The use of common nsNSAIDS during pregnancy is not associated with increased risk of major congenital malformations, structural heart defects or difference in infant survival (**N**) (**Level III-2**).
5. Exposure to an nsNSAID or coxib is not an independent risk factor for spontaneous abortion (**Q**) (**Level III-2**)
6. The safety of alpha-2-delta ligand use in pregnancy remains unclear; limited data has not raised safety concerns (**N**) (**Level III-2**).

☑ For pain management in pregnancy, nonpharmacological treatment options should be considered where possible before analgesic medications are used (**U**).

☑ Use of medications for pain in pregnancy should be guided by published recommendations; ongoing analgesic use requires close liaison between the patient, the health professional managing the pregnancy and the health professional managing the pain (**U**).

☑ Most of the data reported in this setting are from episodes of prolonged use (eg for chronic conditions) and there is a lack of data on the risk of short-term exposure such as in the treatment of acute pain (**N**).

☑ Studies of analgesic use during pregnancy may be confounded by the indication, recall bias and often the lack of an active comparator; this is exemplified by reported associations between NSAID use in pregnancy and low birth weight and asthma confounded by the maternal indications for their use (ie inflammatory diseases) (**N**).

☑ Nonselective NSAIDs and Coxibs should be used with caution in the last trimester of pregnancy and should be avoided after the 32nd week (**U**).

☑ Emerging evidence suggests that maternal paracetamol use may influence premature closure of the fetal ductus arteriosus (**N**).

☑ Neonates exposed to regular opioid in utero, particularly in the last three months of pregnancy, are at risk of neonatal abstinence syndrome and should be monitored for it after delivery (N).

Pain syndromes in pregnancy

1. Exercise reduces low back and pelvic girdle pain during pregnancy (**S**) (**Level I** [Cochrane Review]).
2. Manual therapy interventions reduce intensity of pregnancy-related back and pelvic pain versus usual care and relaxation, but not to sham interventions (**N**) (**Level I** [PRISMA])

☑ The use of a pelvic support belt may reduce pelvic girdle pain during pregnancy (**N**).

Management of acute pain during labour and after birth

Neuraxial and regional analgesia for pain in labour

1. Epidural and combined spinal-epidural analgesia provides superior pain relief for labour and delivery compared with all other analgesic techniques (**S**) along with improved maternal satisfaction (**R**) (**Level I** [Cochrane Review]).
2. Epidural analgesia compared to systemic opioid reduces maternal nausea and/or vomiting (**N**) and need for maternal oxygen supplementation (**N**), but increases the duration of the first and second stage of labour slightly (**Q**) (**Level I** [Cochrane Review]).
3. Epidural analgesia compared to systemic opioid does not increase the rate of Caesarean section (**S**), long-term backache (**S**), headache (**N**), pruritus (**N**) or postnatal depression (**N**) (**Level I** [Cochrane Review]).
4. Epidural analgesia compared to systemic opioids reduces the risk of fetal acidosis (**S**) and the need for neonatal naloxone administration with no increase in special care/neonatal intensive care unit admissions (**N**) (**Level I** [Cochrane Review]).
5. Epidural analgesia may increase the rate of assisted vaginal delivery (**U**), but not with contemporary techniques of epidural analgesia (use of low-concentrations of local anaesthetics) (**Q**) (**Level I** [Cochrane Review]).
6. Lower concentrations of local anaesthetics for epidural analgesia in labour result in a shorter duration of second stage of labour, fewer assisted vaginal deliveries, greater ambulation and less urinary retention than higher concentrations (**S**) (**Level I** [Cochrane Review]).

7. Early versus late initiation of epidural analgesia leads to no clinically significant differences in outcome (**S**) (**Level I** [Cochrane Review]).
8. In comparison with epidural analgesia, combined spinal-epidural analgesia reduces time to effective analgesia (**U**), does not increase maternal satisfaction (**U**), increases the incidence of mild pruritus (compared to low-dose epidurals) (**U**) (**Level I** [Cochrane Review]) and reduces the risk of unilateral block (**N**) (**Level I** [PRISMA]).
9. Local anaesthetic nerve blocks (in particular paracervical blocks) provide better analgesia than placebo, nonopioids and opioids for labour pain, but at an increased rate of adverse effects (**U**) (**Level I** [Cochrane Review]).
10. Non-reassuring fetal heart rate tracings can be more common with combined spinal-epidural analgesia than epidural analgesia in labour (**N**) (**Level I** [PRISMA]).
11. Ultrasound guidance improves the success of epidural catheter insertion and intrathecal needle placement and reduces traumatic insertions (**N**) (**Level I** [PRISMA]).
12. Patient-controlled epidural analgesia provides effective analgesia for labour (**U**) but optimal settings (**U**) (**Level I**) and the need for a background infusion remain unclear (**U**) (**Level I** [PRISMA]).
13. Programmed intermittent epidural bolus versus continuous epidural infusion reduces the incidence of breakthrough pain without increasing adverse outcome (**S**) (**Level I** [PRISMA]).
14. Dural puncture epidural analgesia does not appear to offer benefit over standard epidural analgesia (N) (**Level I** [PRISMA]).
15. There is no difference between the use of bupivacaine and ropivacaine for epidural analgesia in labour for any outcome (**U**), except ropivacaine may reduce the incidence of motor block (**Q**) (**Level I**).
16. Single-injection intrathecal opioids provide comparable early labour analgesia to epidural local anaesthetics, with increased pruritus but no difference in nausea (**U**) (**Level I**). Adding single injection intrathecal morphine (≤250 mcg) to local anaesthetic combined with shorter acting opioids increases time to first analgesic request, but is associated with increased adverse effects **(N)** (**Level I**).

Systemic analgesia for pain in labour

17. Analgesic concentrations of inhaled volatile anaesthetics provide superior analgesia in labour but more drowsiness, compared to inhaled nitrous oxide (**U**) (**Level I** [Cochrane Review]).
18. Inhaled nitrous oxide has some analgesic efficacy in labour pain (**U**), increases maternal adverse effects (nausea, vomiting, dizziness) (**U**) but has no adverse effects on the newborn (**U**) (**Level I** [Cochrane Review]); pain relief is comparable to pethidine but inferior to epidural analgesia (**U**) (**Level IV SR**).
19. Use of nonopioid analgesics alone for labour analgesia is not supported by current evidence (**U**) (**Level I** [Cochrane Review]).
20. Parenteral opioids other than remifentanil intravenous PCA provide moderate analgesic effects in labour pain (**S**), are inferior to epidural analgesia (**S**) and cause increased adverse maternal effects (sedation, nausea, vomiting) (**S**) and adverse effects on the newborn remain unclear (**Q**) (**Level I** [Cochrane Review]).

21. Remifentanil intravenous PCA is inferior to epidural analgesia (**U**), but provides better analgesia in labour compared to other parenteral opioids (**S**) (**Level I** [Cochrane]).

Complementary and other methods of pain relief in labour

22. Continuous or one-to-one support by a midwife or trained layperson during labour reduces analgesic use, rate of assisted and operative birth and dissatisfaction (**S**) (**Level I** [Cochrane Review]).
23. Immersion in water during labour may reduce the requirements for regional and neuraxial analgesia, with no difference in other maternal outcomes and insufficient evidence for neonatal outcomes compared to no immersion (**W**) (**Level I** [Cochrane Review]).
24. Relaxation by use of yoga, music or audio has limited benefit for pain relief or satisfaction in labour (**Q**) (**Level I** [Cochrane Review]).
25. Acupuncture and acupressure for labour pain may reduce pain, use of pharmacological pain relief and increase satisfaction with pain management vs standard care or placebo (**Q**) (**Level I** [Cochrane Review]); Caesarean section rates are unchanged (**R**) (**Level I** [Cochrane Review]).
26. Acupressure (vs sham) reduces labour pain, but has no effect on the use of pharmacological analgesia (**Q**) (**Level I** [Cochrane Review]).
27. Massage may decrease pain in the first stage of labour pain compared to standard care (**S**) (**Level I** [Cochrane Review]).
28. Transcutaneous electrical nerve stimulation has no effect on pain, interventions or outcomes in labour (**U**) (**Level I** [Cochrane Review]).
29. Biofeedback, sterile water injections intra- or subcutaneously and aromatherapy have no effect on labour pain or other outcomes (**U**) (**Level I** [Cochrane Review]).
30. Use of a birth ball may improve labour pain (**N**) (**Level I**).
31. Heat packs may reduce labour pain during the first and second stages (**N**) (**Level I** [Cochrane Review]).
32. Hypnosis (mostly antenatal interventions) may reduce analgesic requirements for labour pain (**R**) (**Level I** [Cochrane Review]).

Pain relief after Caesarean section

33. Local anaesthetic wound infiltration, in particular abdominal nerve blocks, reduces opioid consumption following Caesarean section (**U**) (**Level I** [Cochrane Review]).
34. Local anaesthetic transversus abdominis plane blocks reduce postoperative opioid requirements and pain scores after Caesarean section but only when intrathecal morphine is not used (**S**) (**Level I** [PRISMA]).
35. In relation to controls only and with no direct comparison between the two approaches, local anaesthetic transversus abdominis plane blocks performed by a posterior approach provide a longer duration of benefit versus the lateral approach after lower abdominal incision surgery including Caesarean section (**U**) (**Level I** [PRISMA]).
36. Intravenous paracetamol given before incision reduces opioid analgesic requirements after Caesarean section (**N**) (**Level I** [PRISMA])

37. Epidural (**U**) (**Level I** [QUOROM]) and intrathecal morphine (**U**) (**Level I**) and patient-controlled epidural analgesia (**U**) (**Level II**) provide effective analgesia after Caesarean section, but neuraxial morphine increases the rate of pruritus and nausea compared with systemic administration (**U**) (**Level I** [QUOROM]).

38. Intrathecal morphine (range of 100 mcg to 250 mcg) increases time to first analgesic request after Caesarean section, but pain scores and opioid consumption are unchanged, and postoperative nausea, vomiting and pruritus increased (**N**) (**Level I**).

☑ Remifentanil IV PCA for relief of labour pain carries a risk of maternal respiratory depression; use is recommended only if there is one-on-one continuous presence of a midwife, continuous oxygen saturation monitoring and continuous cardiotocograph monitoring (as an indirect method of detecting global hypoxaemia) (**U**).

☑ Transversus abdominis plane blocks after Caesarean section may result in high plasma concentrations of local anaesthetic and potential toxicity; minimum effective doses should be used (**U**).

Pain management during lactation

1. Local anaesthetics, paracetamol and several NSAIDs, in particular ibuprofen, are considered to be safe in the lactating patient (**U**) (**Level IV**).

2. Morphine, fentanyl, methadone, and short-term oxycodone immediately after delivery are considered to be safe in the lactating patient and are preferred over pethidine (**U**) (**Level IV**).

3. Repeated dosing of codeine or oxycodone in lactating patients should be avoided if possible and the infant monitored for central nervous system depression (**S**) (**Level IV**).

☑ Prescribing medications during lactation requires consideration of possible transfer into breast milk, uptake by the infant and potential adverse effects for the infant; it should follow available prescribing guidelines (**U**).

☑ Breastfed neonates and infants may become sedated from the transfer of maternal medications; in this case, observation and monitoring of the infant and seeking medical advice is warranted. Maternal sedation may be an early warning sign (**N**).

Pain in the puerperium

1. Routine episiotomy does not reduce perineal pain (**U**) (**Level I** [Cochrane Review]).

2. Continuous suturing of all layers compared with interrupted suturing for repair of episiotomy or second-degree tears reduces perineal pain and analgesic use in the postpartum period (**U**) (**Level I** [Cochrane Review]).

3. Paracetamol and NSAIDs are effective in treating perineal pain after childbirth compared with placebo (**S**) (**Level I** [Cochrane Review]).

4. NSAIDs, but not paracetamol, are effective in treating pain from uterine cramping after vaginal birth (**U**) (**Level I** [Cochrane Review]).

5. There is limited evidence to support the effectiveness of local cooling treatments in treatment of perineal pain after childbirth (**U**) (**Level I** [Cochrane Review]).

6. Topical local anaesthetic preparations are not effective for perineal pain after childbirth (**U**) (**Level I** [Cochrane Review]).
7. There is insufficient evidence to recommend any specific treatments for nipple pain and breast engorgement (**U**) (**Level I** [Cochrane Review]).

☑ Pain after childbirth requires appropriate treatment as it coincides with new emotional, physical and learning demands and may trigger postnatal depression (**U**).

☑ Management of breast and nipple pain should target the cause (U).

The older patient

1. Topical nsNSAIDs for localised pain provide effective analgesia (**U**) (**Level I** [Cochrane Review] with lower plasma concentrations and fewer gastrointestinal adverse effects than oral nsNSAIDs (**U**) (**Level I**); this may improve safety in the elderly.
2. PCA and epidural analgesia are more effective in older people than conventional opioid regimens (**U**) (**Level II**).
3. Experimental pain thresholds to thermal stimuli are modestly increased in older people (**U**) (**Level III-2 SR**).
4. Reported frequency and intensity of acute pain in clinical situations may be reduced in the older person (**U**) (**Level III-2**).
5. Common unidimensional self-report measures of pain can be used in the older patient in the acute pain setting, but need to be appropriate for the individual patient; the verbal descriptor and numerical rating scales are preferred in patients who can self-report (**U**) (**Level III-2**), while in the older patient with cognitive impairment, specific pain assessment tools are more appropriate (**N**) (**Level IV SR**).
6. Undertreatment of acute pain is more likely to occur in cognitively impaired patients (**U**) (**Level III-2**).
7. The use of nsNSAIDs and coxibs in older people requires caution, although use of opioids may result in more complications (**U**) (**Level III-2**); paracetamol is the preferred nonopioid analgesic (**U**) (**Level III-2**).
8. The under-representation of older patients in clinical drug trials limits information about efficacy, safety and pharmacokinetics of many types of medications including analgesic medications **(N) (Level IV SR**}
9. The older patient is at increased risk from adverse effects of medications including many analgesics (**N**) (**Level IV**).
10. Delirium is common in elderly hospitalised patients, including after surgery; risk factors include inadequate pain management and excessive use of opioids and other sedating analgesics (**N**) (**Level IV**).
11. There is an age-related decrease in opioid requirements; significant interpatient variability persists (**U**) (**Level IV**).
12. The age-related decrease in opioid requirements is related more to the changes in pharmacodynamics that accompany ageing than to the changes in pharmacokinetics (**U**) (**Level IV).**

☑ The assessment of pain and evaluation of pain relief therapies in the older patient may present problems, arising from differences in reporting, cognitive impairment and difficulties in measurement (**U**).

☑ Measures of present pain may be more reliable than past pain, especially in patients with some cognitive impairment (**U**).

☑ The physiological changes associated with ageing are progressive; while the rate of change can vary markedly between individuals and is related to frailty, these changes may decrease the dose (maintenance and/or bolus) of drug required for pain relief and may lead to increased accumulation of active metabolites (**U**).

☑ The high prevalence of frailty in the older patient is an independent risk factor for increased adverse drug effects to analgesic medications (**N**).

☑ The use of regional analgesics techniques, as an alternative to systemic analgesics, can confer benefits of improved pain relief, and minimise adverse effects (cognitive, pulmonary) (**N**).

☑ Cognitive impairment in the older patient may limit the appropriate use of PCA (**N**).

Culturally responsive care for Culturally and Linguistically Diverse patients

1. Disparities in assessment, analgesic requirements and effective treatment of pain exist across ethnic groups (**S**) (**Level III-2 SR**).
2. Ethnic and cultural background of both healthcare professional and patient can influence the ability to assess and treat acute pain (**N**) (**Level III-2 SR**).

☑ Cultural competence of health professionals supported by specific training improves health outcomes for culturally and linguistically diverse patients (**U**).

☑ Pain assessment and management should be done on an individual patient basis. Differences between ethnic and cultural groups should not be used to stereotype patients but should only be used to inform of possible cultural preferences (**U**).

☑ Multilingual printed information and pain measurement scales are useful in managing patients from different cultural or ethnic backgrounds (**U**).

☑ If language proficiency poses a communication barrier, then an accredited health care interpreter should be included when conducting a pain assessment, to ensure correct assessment; the use of friends, family or staff member should be avoided (**N**).

☑ The use of health-care specific language translation apps may be only considered as an alternative option in non-clinical situations in the sub-acute setting (eg daily routine communication) when formal healthcare interpreter services are not available (**N**).

Aboriginal and Torres Strait Islander Peoples

1. Verbal descriptor scales may be a better choice of pain measurement tool than verbal numerical rating scales in some Aboriginal and Torres Strait Islander Peoples (**U**) (**Level III-3**).
2. Medical comorbidities such as renal impairment are more common in Aboriginal and Torres Strait Islander Peoples and may influence the choice of analgesic agent (**U**) (**Level IV**).

☑ Heterogeneity between differing populations of Aboriginal Peoples may require tailoring of the service delivered to the population and individual being serviced (**U**).

☑ Pain expression in Aboriginal and Torres Strait Islander Peoples may not reflect that which is expected by the health professional's cultural background. This places the onus on the health professional to understand nuances of pain expression and beliefs within such populations (**U**).

☑ Aboriginal and Torres Strait Islander Peoples are at increased risk of underrecognition and undertreatment of pain (**N**).

Māori peoples

1. Experimental ischaemic pain is tolerated for longer in Māori people than in European New Zealanders (**U**) (**Level III-2**).
2. Māori people report higher levels of pain and/or disability with dental pain, gout and after trauma and joint replacement surgery than European New Zealanders (**U**) (**Level III-2**).

☑ High healthcare inequalities exist regarding access and quality of care (across age ranges, genders and for various medical conditions) between the Māori and Pacific Islander peoples compared with New Zealanders of European origin (**S**).

☑ Māori culture embraces the multidimensional aspects of pain experiences (**S**).

The patient with sleep-disordered breathing including obstructive sleep apnoea

1. Continuous pulse oximetry compared to intermittent nursing spot-checks detects more episodes of hypoxaemia in postoperative patients with obstructive sleep apnoea prescribed opioids (**N**) (**Level I**).
2. The STOP-Bang questionnaire has high sensitivity for the identification of patients at risk of moderate to severe obstructive sleep apnoea (**S**) (**Level III-2 SR**).
3. Patients with sleep-disordered breathing, including obstructive sleep apnoea, having surgery are at increased risk of adverse cardiac and respiratory effects (**S**) (**Level III-2 SR**), in particular cardiac arrest/shock, atrial fibrillation, aspiration pneumonia, acute respiratory distress syndrome and need for intubation, mechanical and noninvasive ventilation (**N**) (**Level III-2**) and increased hospital length of stay (**N**) (**Level III-2 SR**).
4. Patients with obstructive sleep apnoea have an increased risk of exacerbation of obstructive episodes and hypoxaemia during the postoperative period (**U**) (**Level III-2**), in particular in the first 72 hours with peaks on the first and third postoperative night (**N**) (**Level III-2**).
5. Morbidly obese patients may be at increased risk of postoperative hypoxaemia, independent of a diagnosis of obstructive sleep apnoea (**U**) (**Level III-2**).
6. Continuous positive airway pressure does not increase the risk of anastomotic leak after upper gastrointestinal surgery (**S**) (**Level III-2**).
7. Increasing severity of obstructive sleep apnoea is associated with increased risk of postoperative respiratory complications including opioid-induced ventilatory impairment (**Q**) (**Level III-3**).
8. The prevalence of obstructive sleep apnoea in the surgical patient population is high and the majority (80%) of these patients are undiagnosed (**S**) (**Level IV SR**).

9. Higher preoperative apnoea-hypopnoea index and identification of nocturnal hypoxemia are risk factors associated with postoperative complications in patients with sleep-disordered breathing (**N**) (**Level IV SR**).
10. Patients with obstructive sleep apnoea have increased sensitivity to pain that improves with use of continuous positive air way pressure (**N**) (**Level IV SR**).
11. Opioids in patients with obstructive sleep apnoea attenuate arousal to hypoxia and prolong airway obstruction, and thereby lead to more severe hypoxaemia (**S**) (**Level IV SR**).

☑ Preoperative screening for obstructive sleep apnoea combined with treatment (ideally instituted preoperatively) and increased postoperative observation may decrease postoperative morbidity and mortality (**S**).

☑ Management strategies that may increase the efficacy and safety of pain relief in patients with obstructive sleep apnoea include multimodal nonsedating opioid-sparing analgesia such as regional techniques, continuous positive airway pressure, monitoring and supervision (in a high-dependency area if necessary) and supplemental oxygen (**U**).

☑ Perioperative commencement of continuous positive airway pressure may be beneficial in patients with obstructive sleep apnoea but requires high levels of supervision; significant problems are poor patient acceptance and postoperative adherence (**U**).

☑ In patients with obstructive sleep apnoea, monitoring should be extended beyond 24 hours to capture the high-risk period for late postoperative hypoxaemia (**N**).

The obese patient

1. Perioperative dexmedetomidine infusion reduces pain intensity, opioid requirements and PONV after bariatric surgery (**N**) (**Level I** [PRISMA]).
2. Intraoperative peritoneal local anaesthetic administration reduces pain intensity and opioid requirements after bariatric surgery (**N**) (**Level I** [PRISMA]).
3. Paracetamol (multi-dosing) r educes opioid requirements, hospital length of stay and representations for pain after bariatric surgery (**N**) (**Level II**).
4. Intraoperative systemic lidocaine infusions reduce pain intensity, opioid requirements and improve the quality of recovery after bariatric surgery (**N**) (**Level II**).
5. Epidural administration of local anaesthetics in obese patients has been associated with increased risk of cephalad spread (**N**) (**Level III-2**).
6. Obesity increases the failure rate of neuraxial and peripheral nerve blocks (**N**) (**Level IV**); ultrasound guidance improves the success rate (**N**) (**Level IV**).

☑ Obesity has significant detrimental effects on respiratory function and is linked to an increased rate of obstructive sleep apnoea (**N**).

☑ Obesity influences pharmacokinetic and pharmacodynamic parameters of analgesic medications leading to uncertainty about dosing and caution should be used with weight-based dosing (**N**).

☑ Multimodal analgesic techniques including use of regional techniques result in opioid-sparing effects and thereby improve safety of acute pain management after bariatric surgery (N).

The patient with concurrent renal or hepatic disease

☑ Consideration should be given to the choice and dose regimen of analgesic agents in patients with hepatic and particularly renal impairment (**S**).

The opioid-tolerant patient

1. Alpha-2 agonists (clonidine and lofexidine) reduce opioid-withdrawal symptoms (**U**) (**Level I** [Cochrane Review]).
2. Remifentanil use leads to opioid-induced hyperalgesia (**U**), which is attenuated by propofol (**U**) (**Level I** [PRISMA]), NMDA-receptor antagonists (**U**) (**Level I** [QUOROM]), pregabalin (**U**) (**Level II**), nitrous oxide (**N**) (**Level II**) and gradual tapering of remifentanil dose (**N**) (**Level II**).
3. Gabapentin and pregabalin attenuate opioid-induced hyperalgesia/tolerance and reduce opioid-withdrawal symptoms (**U**) (**Level II**).
4. In opioid-tolerant patients, ketamine improves pain relief after surgery and reduces opioid requirements (**S**) (**Level II**).
5. Long-term opioid use is a dose-dependent risk factor for sleep-disordered breathing, which requires appropriate perioperative assessment, monitoring and management (**S**) (**Level III-2 SR**).
6. Long-term opioid use is associated with dose-dependent increased risks of injuries (**N**) (**Level III-2**) including fractures (**N**) (**Level III-2 SR**) and overdose (**N**) (**Level III-2**).
7. Preoperative opioid use is associated with worse outcomes after a variety of operations (**N**) (**Level III-2**).
8. Preoperative opioid tapering may ameliorate the risk of postoperative complications and morbidity (**N**) (**Level III-2**)
9. Preoperative opioid use is a risk factor for prolonged postoperative opioid use (**N**) (**Level III-2**).
10. Opioid-tolerant patients report higher pain scores, have slower pain resolution leading to longer hospital stay and increased readmissions but have a lower incidence of opioid-induced nausea and vomiting (**U**) (**Level III-2**).
11. Opioid-tolerant patients may have significantly higher opioid requirements and interpatient variation in the doses needed than opioid-naïve patients (**U**) (**Level III-2**).

☑ Usual preadmission opioid regimens should be maintained where possible or appropriate substitutions made (**S**).

☑ Liaison with all health care professionals involved in the treatment of the opioid-tolerant patient is important (**S**).

☑ Opioid-tolerant patients are at risk of opioid withdrawal if nonopioid analgesic regimens, tramadol or tapentadol alone are used (**U**).

☑ PCA settings may need to include a background infusion or other background opioid to replace the usual opioid dose and a higher bolus dose (**U**).

☑ Neuraxial opioids can be used effectively in opioid-tolerant patients, although higher doses may be required and these doses may be inadequate to prevent withdrawal (**U**).

☑ Adjuvants are used for their antitolerance, antihyperalgesic, and antiallodynic effects and there is some evidence upon which to base the choice of agent (**S**).

☑ In patients with escalating opioid requirements, management considerations are the development of tolerance or opioid-induced hyperalgesia (**S**).

☑ Following short-term opioid dose escalation for acute pain, a "reverse analgesic ladder" approach, using stepwise reduction to the patient's usual opioid regimen is recommended (**S**).

☑ For assessment of withdrawal reactions, the use of a validated withdrawal tool in opioid-tolerant patients is recommended; management strategies vary and include weaning, rotation and adjuvant use (**N**).

The patient with a substance use disorder

1. Benzodiazepines are effective for alcohol-withdrawal symptoms, in particular reducing seizures (**U**) (**Level I** [Cochrane Review]).
2. Opioid substitution therapy with methadone or buprenorphine is better than clonidine and lofexidine in ameliorating withdrawal symptoms (**N**) (**Level I** [Cochrane Review]).
3. Methadone and buprenorphine maintenance regimens should be continued throughout acute pain episodes wherever possible (**S**) (**Level III-2 SR** [PRISMA]).
4. Poorly managed acute pain episodes may decrease retention in opioid-maintenance programs (**U**) (**Level III-2**).
5. To achieve better analgesic efficacy, daily methadone maintenance doses should be divided and given 8 to 12 hourly (**S**) (**Level IV SR** [PRISMA]).

☑ Pain management in patients with substance use disorder often presents significant challenges for both clinicians and patients. Patients fear being stigmatised or discriminated against, are concerned about inadequate pain relief with their past experiences leading to physician distrust; they fear experiencing withdrawal (before their usual drugs are prescribed) and relapse precipitated by acute opioid exposure. The challenges for the clinician Include mistrust, concerns about drug seeking, fear of overtreatment with adverse events, concerns about diversion, and risk of discharge against medical advice (**N**).

☑ A "universal precautions" approach is increasingly recommended for patients with substance use disorder in acute pain settings; it may include use of multimodal analgesia, abuse-deterrent formulations, urine drug screening, use of prescription drug monitoring programs and risk management strategies (**N**).

☑ An acute admission offers opportunity to engage with patients with substance use disorder as well as to treat the acute issues (**N**).

☑ There is no cross-tolerance between alcohol or benzodiazepines or central nervous system stimulants and opioids (**U**).

☑ Oral naltrexone should be stopped at least 24 hours, ideally 72 hours, prior to elective surgery (**U**); naltrexone implants may need surgical removal in cases of severe acute pain where opioid responsiveness is required (**U**).

☑ Patients who have ceased naltrexone therapy should be regarded as opioid naïve; in the immediate post-treatment phase they may be more opioid sensitive (**U**).

☑ To achieve better analgesic efficacy, daily buprenorphine maintenance doses could be divided and given 8 to 12 hourly (**U**).

☑ Nicotine has a small to medium analgesic effect in volunteers and smoking abstinence increased self-reported pain (**N**).

10.0 | Paediatric

Developmental neurobiology of pain

1. Following birth, even the most preterm neonate responds to nociceptive stimuli (**U**) (**Level IV**).
2. In early development, more generalised reflex nociceptive responses occur in response to lower intensity stimuli (**U**) (**Level IV**).

Consequences of early pain and injury

1. Pain and injury in early life cause structural changes in cortical and subcortical pathways and are associated with alteration in somatosensory thresholds in later life (**U**) (**Level III-2**).
2. Analgesia may modulate the long term effects of pain and injury in early life but more information is required to determine the optimal dosing and type of agents to avoid negative impact of the pharmacological intervention itself (**U**) (**Level III-2**).
3. Improving quality of infant pain management delivery in neonatal intensive care (including pharmacological and nonpharmacological interventions) may result in improved neurodevelopmental outcomes (**U**) (**Level III-2**).
4. Understanding of the epigenetic factors that contribute to the behavioural pain trajectory is evolving; this may lead to enhanced developmentally targeted care to reduce stress exposure and long term impacts for infants (**N**) (**Level IV SR** [PRISMA]).

Paediatric pain assessment

1. Pain measurement tools are available for children of all ages (**S**) (**Level IV SR**).
2. Paediatric pain measurement tools must be matched to the age and development of the child (**U**) (**Level IV SR**).
3. Adoption of written guidelines or pain management algorithms improves both assessment and management of pain in neonates and children (**N**) (**Level IV SR**).

☑ Pain assessment and measurement are important components of paediatric pain management (**U**).

☑ Pain scores generated from different pain scales may not be congruent and this should be considered when used clinically and in research (**N**).

☑ Pain scores and pain score subdivisions (cut-offs) should not be used as a sole guide to administration of analgesia (**N**).

☑ Children with neurodevelopmental disorders (with and without cognitive impairment and varying levels of physical disability) may be more susceptible to pain and communicate it in different ways (**N**).

☑ Pain measurement tools must be appropriate for the clinical context, be explained and used consistently (**U**) and be validated when translated into other languages (**Q**).

☑ Facial recognition software applications may reduce clinician bias and become useful bedside tools in neonates and children with and without cognitive impairment (**N**).

Analgesic agents

Paracetamol (acetaminophen)

1. Post tonsillectomy in children, paracetamol (alone or combined with opioids) administered as required compared to fixed schedule achieved similar pain scores over 3 days; with lower dosing administered in the as required groups (**N**) (**Level I** [Cochrane Review]).
2. For pain of acute otitis media in children, paracetamol is similar to ibuprofen and both are superior to placebo in achieving pain freedom at 48 hours, but not other time points (**N**) (**Level I** [Cochrane Review]).
3. Paracetamol is effective for moderately severe pain and decreases opioid requirements after major and minor surgery in children (**U**) (**Level I** [PRISMA]).
4. Paracetamol has a similar safety and tolerability profile compared with ibuprofen and placebo if prescribed and administered at recommended doses in children (**U**) (**Level IV SR**).
5. Retrospective epidemiological studies linking paracetamol use in pregnancy or infancy to later development of childhood asthma are inherently confounded (**U**); when adjusted for respiratory tract infections in the child the association is lost (**Q**) (**Level III-2 SR** [PRISMA]).
6. Retrospective epidemiological studies report modest association of paracetamol use in pregnancy with childhood neurodevelopmental disorders such as attention deficit and hyperkinetic disorders; this is strengthened when adjusted for longer term use (>28 days) and disappears for short term use (<8 days) (**Q**) (**Level III-2 SR** [PRISMA]).
7. Paracetamol has unclear vasoactive effects; in critically ill children, hypotension is reported with both IV formulations (**N**) (**Level IV SR**).

☑ Safe dosing of paracetamol requires consideration of the age and body weight of the child and the duration of therapy (**U**).

☑ Paracetamol related hepatotoxicity generally occurs in children who have received doses greater than 120 mg/kg, as single or repeated daily dosing; with contributions from rounding up or 10-fold dosing error and formulation substitution or confusion by prescribers and parents (**N**).

☑ Paracetamol is recommended routinely following tonsillectomy and pharmacokinetic/pharmacodynamic simulation is exploring the optimal combinations of multimodal analgesia in this surgical model (**N**).

☑ There is insufficient pharmacokinetic/pharmacodynamic and safety data of use of paracetamol in preterm and term neonates; use for patent ductus arteriosus closure in preterm neonates provides limited data in this age group of an improved safety profile compared with nsNSAIDs (**N**).

☑ Emerging evidence suggests that maternal paracetamol use may influence premature closure of the fetal ductus arteriosus (**N**); use in pregnancy should be limited to the minimum dose and duration that is clinically necessary.

☑ Intravenous paracetamol in haemodynamically unstable patients has been associated with hypotension (**N**).

Nonselective NSAIDs

1. Nonselective NSAIDs do not increase the risk of either surgical or nonsurgical intervention for bleeding after paediatric tonsillectomy (**U**) (**Level I** [Cochrane Review]); however this was not supported by a large non-inferiority RCT where surgical intervention was increased with ibuprofen versus paracetamol (**Q**) (**Level II**).
2. Nonselective NSAID (ibuprofen) use for acute otitis media reduces pain (at 48 hours) vs placebo, with similar efficacy to paracetamol (**N**) (**Level I** [Cochrane Review]).
3. Nonselective NSAIDs are effective for moderately severe pain and decrease opioid requirements after major paediatric surgery (**U**) (**Level I** [PRISMA]) and postoperative nausea and vomiting (**U**) (**Level I** [QUOROM]).
4. Serious adverse effects after nonselective NSAIDs are rare in children over 6 months of age (**U**) (**Level II**).
5. Ibuprofen may increase severity of haemorrhage post tonsillectomy in patients returning to theatre (**N**) (**Level III-3**).
6. Short term use of ketorolac or ibuprofen do not increase bone healing complications in children undergoing posterior spinal fusion, osteotomy, or fractures managed surgically (**S**) (**Level III-3**) or conservatively (**N**) (**Level III-3**).

☑ Aspirin for acute pain indications should be avoided in children (**U**).

☑ Combined population pharmacokinetic-pharmacodynamic modelling is required to inform targeted dosing recommendations of analgesics in children (**U**).

Coxibs

1. Parecoxib use in children reduces early postoperative pain scores, PONV (compared to tramadol and fentanyl) and postoperative opioid consumption (**N**) (**Level I** [PRISMA]).
2. Parecoxib may have a ceiling analgesic effect in children in doses less than 1 mg/kg (**N**) (**Level II**).

☑ The safety profile of coxibs in the setting of allergy or contraindication to nonselective NSAID in adults and children is encouraging; but safety data specific to short term use in the perioperative period is limited (**Q**).

☑ Celecoxib for 3 days reduces pain and additional analgesic requirement post-tonsillectomy in children (**N**).

☑ Some paediatric centres retain the 1 mg/kg (40 mg) maximum daily dosing schedule for Parecoxib for off license use (**N**).

Conventional and atypical opioids

Opioids

1. Young and obese children with history of obstructive sleep apnoea/sleep-disordered breathing are at higher risk of developing serious opioid-induced ventilatory impairment and death (**U**) (**Level IV**).
2. Opioid-induced ventilatory impairment and death occur rarely with therapeutic dosing in children taking opioids at home (**N**) (**Level IV**).
3. Safe dosing of opioids requires consideration of the child's age, body weight, comorbidities and ethnicity (**U**) (**Level IV**).

Fentanyl

4. Intranasal fentanyl is an effective treatment for paediatric acute pain management, with an acceptable adverse effect profile and ease of delivery (**N**) (**Level I**).

Codeine

5. The efficacy of oral codeine in children is unpredictable due to genetic differences in the ability to generate the active metabolite morphine (**U**) (**Level II**), as are adverse effects and serious toxicity (**U**) (**Level IV**).
6. Codeine should not be used in children, especially after adenoidectomy or tonsillectomy, due to an increased risk of opioid-induced ventilatory impairment and death (**S**) (**Level IV**).

Tramadol

7. Tramadol provides superior analgesia to placebo and has similar efficacy to conventional opioids in children of all ages administered by various routes for multiple surgery types (**S**) (**Level I** [Cochrane]).
8. It is unclear if tramadol causes less ventilatory impairment than other opioids in children due to insufficient trial size (**N**) (**Level I** [Cochrane]).

Buprenorphine

9. Buprenorphine administered IV or caudally has similar efficacy to morphine or caudal local anaesthetic in children for different surgery types (**N**) (**Level II**).

Nalbuphine

10. Nalbuphine intravenously is effective for postoperative pain relief in children in several low quality heterogeneous trials (**N**) (**Level I** [Cochrane]).

☑ Careful titration of opioids is advised according to the individual child's response (analgesia and adverse effects) (**U**).

☑ Despite the regulatory response with boxed warning and upscheduling of codeine, prescription continues in at risk patients (with obstructive sleep apnoea/sleep-disordered breathing or post adenotonsillectomy) or has been replaced by prescription of potent conventional opioids such as oxycodone and hydrocodone which present similar or greater hazard (**N**).

☑ The practice of applying an occlusive dressing to the skin surface of a transdermal fentanyl delivery system does not limit dose delivery (**U**).

☑ Tramadol shares some adverse effects with the conventional opioid class in children, with similar or reduced rates of nausea and vomiting, sedation and fatigue but less constipation

and pruritus (**U**). Sedation (not necessarily associated with miosis), seizures, ventilatory impairment and deaths have occurred (**N**).

☑ Naloxone has been used to treat tramadol overdose in children with effect (**N**).

☑ CYP2D6 phenotype has been the reason for codeine's black box warning, but the clinical significance in terms of tramadol/M1's analgesic efficacy and adverse-effect profile including safety is still unknown (S). Inadvertent overdose and formulation issues are likely of greater risk than CYP phenotypes resulting in variable drug metabolism; evidence for harm from this second mechanism is lacking (**N**).

☑ Tramadol 100mg/mL concentrated drops formulation use is potentially harmful in children with possible dosing confusion (drops with millilitres) and resultant overdose (**U**).

☑ In paediatric overdose, buprenorphine causes the spectrum of neurocognitive adverse events as seen with conventional opioids which may be reversible with naloxone (**N**).

☑ More studies are required to determine tapentadol's comparative efficacy in paediatric acute pain and if its adverse effect profile in children is improved versus placebo, conventional opioids or tramadol (**N**).

☑ In paediatric overdose, tapentadol causes the spectrum of neurocognitive adverse events seen with conventional opioids, which may be reversible with naloxone (**N**).

Discharge opioid prescribing for children

1. Postoperative opioid therapy in children and adolescents may lead to long term opioid use and misuse in later life (**N**) (**Level III-2**); risk factors include type of surgery, psychological and social factors and other substance use (**N**) (**Level III-2**).
2. Long term opioid use following therapeutic medical prescription is uncommon in children and adolescents (**N**) (**Level IV**). However, prior diagnosis of chronic pain, substance use or mental health conditions are risk factors (**N**) (**Level IV**).
3. Misuse of prescription opioids is common amongst adolescents and young adults either as medical use (self-treatment) or nonmedical use (sensation seeking/recreational) (**N**) (**Level IV**).
4. Leftover prescribed opioids are a common source of nonmedical opioid use in adolescents, with most adolescents gaining access through family or friends (**N**) (**Level IV**).
5. Unsafe storage of prescription opioids in the home and non-disposal of leftover opioids is common (**N**) (**Level IV**).
6. Prescription opioids are a large source of opioid-related poisonings: usually accidental in young children and related to recreational use or with intentional overdose in adolescents (**N**) (**Level IV**).
7. Adverse drug events in children and adolescents sent home with prescription opioids are common (**N**) (**Level IV**).

☑ As for adults, a sensible approach should be used in the setting of prescribing discharge opioid medications for children and to adults with children at home (**N**).

☑ As for adults, prescribing discharge medications for children should be done with consideration of the child's anticipated opioid requirements. The tablet number and volume of opioid solution prescribed should be judicious and individualised (**N**).

☑ Understanding and education is required to determine procedure specific pain trajectories in children (**N**).

☑ Carer/parental, patient and clinical staff education is necessary about risks of opioids and how to safely dispose of unused medication by return to a pharmacy (**N**).

☑ Carer/parental and patient education in case of ongoing pain and analgesic issues is appropriate with follow-up by general practitioners or pain medicine services as indicated (**N**).

☑ Education and guidelines are desirable for adult and paediatric discharge and community opioid prescribers with focus on information provision for staff delivering the advice (ideally written and verbal combined) to carers and families (**N**).

Opioid tolerance in children and adolescents

1. Iatrogenic withdrawal syndrome following prolonged inpatient intravenous opioid therapy in critically ill children is common (**N**) (**Level IV SR** [PRISMA]).

☑ There are groups of paediatric patients who are opioid-tolerant, as in adults. They require special consideration for inpatient pain management and perioperative care. In children with opioid tolerance, inadequate pain relief and withdrawal (if opioids are acutely ceased) are specific risks. Acute pain service input can assist with preadmission planning and use of various adjuvants beyond standard multimodal interventions (**N**).

☑ For assessment of withdrawal reactions, the use of a validated withdrawal tool in paediatric opioid-tolerant patients is recommended; management strategies vary and include opioid weaning, rotation and adjuvant use (**N**).

Systemic NMDA-receptor antagonists

Ketamine

1. Perioperative low-dose intravenous ketamine bolus is similarly effective to opioids and superior to placebo in reducing early pain scores and analgesic requirements in children (**U**) (**Level I** [PRISMA]).
2. Perioperative low-dose intravenous ketamine bolus does not increase the postoperative incidence of nausea and vomiting, sedation, agitation, dreams or hallucinations in children (**S**) (**Level I** [PRISMA]).
3. Peritonsillar infiltration and topical application of ketamine for paediatric tonsillectomy reduces early pain scores and analgesic requirements versus placebo (**S**) (**Level I** [PRISMA]).
4. When added to multimodal analgesia, perioperative ketamine (bolus with or without intra/postoperative infusion) in children is not opioid-sparing vs placebo (**S**), although low postoperative pain scores and small sample sizes mean the meta-analysis is underpowered (**Q**) (**Level I** [PRISMA]).
5. There is low level evidence that combination ketamine and opioid PCA improved pain scores and PCA use post Nuss surgery (**N**) (**Level II**)**.**

☑ High-dose long term ketamine is neurotoxic in animal models. The neurodevelopmental impact in children of subanaesthetic/analgesic doses of ketamine administered by bolus or postoperative infusion is unclear (**U**).

☑ The benefit of perioperative ketamine in preventing remifentanil induced hyperalgesia has not been adequately assessed in paediatric surgery (**U**).

Magnesium

6. Magnesium (intravenous or peritonsillar infiltration) in children for tonsillectomy reduces postoperative rescue medication use, and increases time to first analgesia versus control; magnesium also reduces risk of postoperative emergence agitation and laryngospasm (**N**) (**Level I** [PRISMA]).

7. Magnesium (locally infiltrated) in children reduces late (24 hour) but not early (<1 hour) pain scores post tonsillectomy versus control (**N**) (**Level I** [PRISMA]).

Alpha-2 agonists

1. Preoperative oral clonidine reduces postoperative pain scores and analgesic requirement in children compared to placebo or midazolam but not fentanyl (**U**) (**Level I** [Cochrane Review]).

2. Preoperative oral clonidine reduces postoperative nausea and vomiting in children compared to placebo or midazolam (**U**) (**Level I** [Cochrane Review]).

3. Preoperative intranasal dexmedetomidine reduces postoperative pain scores, rescue analgesic requirements and emergence agitation with minimal adverse effects vs placebo (**N**) (**Level I** [PRISMA]) and mixed comparators (**N**) (**Level I**).

4. Intraoperative dexmedetomidine reduces postoperative pain scores (**U**) (**Level I** [PRISMA]) and need for postoperative rescue analgesia (**Q**) (**Level I**) including opioid (**U**) (**Level I** [PRISMA]) in children compared to placebo, with minimal impact on time to discharge (**N**) (**Level I** [PRISMA]) via intravenous (**S**) (**Level I** [PRISMA]) and intranasal routes (**S**) (**Level I**).

☑ Alpha-2 agonists offer benefits in addition to analgesia in children in the perioperative, intensive care and procedural settings. These benefits include anxiolysis, sedation (MAC sparing), behavioural modification, prevention or treatment of opioid withdrawal (facilitating opioid weaning) (**U**) and reduction of emergence agitation (**S**).

Alpha-2-delta ligands (gabapentinoids)

1. Multi-day perioperative (but not single preoperative) gabapentin dosing reduces postoperative morphine consumption vs placebo following multilevel posterior spinal fusion for adolescents with idiopathic scoliosis (**N**) (**Level II**).

2. Multiday perioperative gabapentin reduces phantom limb pain incidence vs placebo in paediatric oncology amputation surgery (**N**) (**Level II**).

3. Preoperative gabapentin and likely pregabalin improve analgesia after tonsillectomy in children and reduce PONV without increasing adverse effects (**N**) (**Level I** [PRISMA]).

☑ Alpha-2 delta ligands use in children for acute (and chronic) pain conditions is expanding based mostly on expert opinion and case series. The pain indications are similar to those for adults with similar benefit and adverse event profiles (**N**).

☑ Gabapentin and pregabalin are used to manage pruritus and neuropathic pain following burn injury in children (**N**).

☑ The use of alpha-2 delta ligands for the prevention of chronic postsurgical pain in children has not been studied (**N**).

Corticosteroids

1. Single dose intravenous dexamethasone reduces pain post tonsillectomy, postoperative vomiting and time to soft diet commencement in children (**U**) (**Level I** [Cochrane Review]).
2. Intavenous dexamethasone does not increase the overall risk of bleeding post tonsillectomy but increases the risk of reoperation for bleeding in children (S) (**Level I**).
3. Oral dexamethasone (given in addition to antibiotics) shortens the time to onset of pain relief in pharyngitis in children (**U**) (**Level I**).
4. Oral prednisolone multiday course post tonsillectomy does not reduce pain outcomes at day 3 or day 7 or postoperative nausea and vomiting (**N**) (**Level I**).

Systemic lidocaine infusions

1. Perioperative intravenous lidocaine infusion in abdominal surgery in children improved various pain and non-pain related postoperative outcomes (**N**) (**Level II**).

☑ Dosing of perioperative lidocaine infusions have been extrapolated from use in adults and pharmacokinetic study is warranted to determine safe dosing practices in children (**N**).

Opioid infusions and Patient Controlled Analgesia (PCA) in children

1. Addition of a low-dose background infusion to patient controlled analgesia (PCA) bolus results in similar pain scores and total opioid consumption and improves sleep duration in children; numbers are inadequate to assess safety of adding a background (**N**) (**Level I**).
2. In ventilated preterm neonates, routine use of morphine infusions does not affect mortality, duration of ventilation or neurological outcomes (**U**) (**Level I** [Cochrane Review]), including when followed up as older children (**S**) (**Level II**).
3. Postoperative intravenous opioid requirements vary with age in neonates, infants and children (**U**) (**Level II**).
4. Intermittent intramuscular injections are distressing for children and are less effective for pain control than intravenous infusions (**U**) (**Level III-1**).
5. Patient-controlled analgesia (PCA) can provide safe and effective analgesia for children as young as 5 years old (**S**) (**Level III-3**).
6. Intravenous opioids via continuous infusion, nurse-controlled analgesia and parental proxy use of patient controlled analgesia (PCA) devices can be used effectively (**U**) (**Level III-2**) and safely (**N**) (**Level IV**) in children of all ages.
7. Nurse-controlled analgesia (**U**) (**Level III-2**) and parental proxy use of patient controlled analgesia (PCA) devices in children (**U**) (**Level III-3**) may require more rescue interventions (such as naloxone, airway management or intensive care) than PCA, but this may reflect the younger patient population where this technique is offered.
8. Morphine by patient controlled analgesia (PCA) is at least as safe as intermittent nurse administered intravenous morphine (**N**) (**Level IV**).

☑ Initial doses of opioid should be based on the age, weight and clinical status of the child and then titrated against the individual's response (**U**).

☑ Effective patient controlled analgesia (PCA) prescription in children incorporates a bolus that is adequate for control of movement-related pain (**U**).

Paediatric Regional Analgesia

1. Topical local anaesthetic does not adequately control pain associated with circumcision in awake neonates (**U**) (**Level I** [Cochrane Review]).
2. Caudal local anaesthetic, dorsal penile nerve block (**U**) (**Level I** [Cochrane Review]) and ring block (**N**) (**Level II**) provide effective perioperative analgesia for circumcision in infants to adolescents.
3. Caudal local anaesthetic in addition to general anaesthesia for circumcision does not reduce postoperative nausea and vomiting or the need for early rescue or other analgesia in children (infants to adolescents) when compared to parenteral analgesia (**U**) (**Level I** [Cochrane Review]).
4. In acute otitis media, topical local anaesthetic drops are effective in children compared to placebo and equivalent to naturopathic drops (**S**) (**Level I** [Cochrane Review]).
5. For paediatric cleft lip repair, infraorbital nerve block with lidocaine or bupivacaine may reduce postoperative pain versus placebo; duration is increased when opioids are added (with no systemic comparator) (**N**) (**Level I** [Cochrane Review]).
6. Epidural analgesia compared to systemic analgesia after spinal surgery in children improves pain up to 72 hours postoperatively (N) (Level I[Cochrane Review]).
7. Local anaesthetics (by infiltration or nerve block) reduce pain scores post dental procedures (**N**) (**Level I** [PRISMA]).
8. Ketamine added to caudal local anaesthetic for paediatric day-stay surgery prolongs analgesia but not motor block (**U**) (**Level I** [PRISMA]); however concerns regarding neurotoxicity remain.
9. Dexamethasone (caudal, perineural or IV) prolongs the duration of analgesia of local anaesthetic caudal (**N**) (**Level I** [PRISMA]) and peripheral nerve blocks (**N**) (**Level II**).
10. Magnesium added to caudal local anaesthetic blocks improves analgesia in children (**N**) (**Level I** [PRISMA]).
11. Clonidine (**U**) and dexmedetomidine (**N**) improve analgesia in children when added to local anaesthetic caudal blocks, epidural infusions (**Level I** [PRISMA]) and peripheral nerve blocks (**N**) (**Level II**).
12. Peritonsillar dexamethasone or peritonsillar ketamine may reduce pain scores following paediatric tonsillectomy compared to placebo (in trials with no systemic comparator arms) (**N**) (**Level I**).
13. Ultrasound guidance for epidural catheter insertion is a reliable predictor of depth to loss of resistance (or of epidural space), offers visibility of the needle and catheter and may reduce bone contacts (**N**) (**Level IV SR**).
14. In children having cardiac surgery, caudal injections with various medication combinations vs control reduces postoperative analgesia requirements and pain scores (**N**) (**Level IV SR** [PRISMA]).

15. In children having scoliosis surgery, the addition of epidural local anaesthetic infusion to intravenous PCA morphine improves pain scores and patient satisfaction (**U**) (**Level I**) and decreases postoperative nausea (**U**) (**Level II**).
16. Peripheral nerve blocks (**S**) (**Level I** [PRISMA]), wound infiltration and caudal local anaesthetic provide effective analgesia after day-stay paediatric inguinal surgery (**S**) (**Level II**).
17. Epidural infusions of local anaesthetic in children provide similar levels of analgesia compared to systemic opioid infusion (**U**) (**Level II**) and intravenous PCA (**U**) (**Level III-3 SR**).
18. Epidural opioids alone are less effective than epidural local anaesthetic or combinations of local anaesthetic and opioid in children (**U**) (**Level II**).
19. Intrathecal opioids provide prolonged analgesia after surgery in children and reduce blood loss during paediatric spinal fusion (**U**) (**Level II**). High doses of intrathecal morphine in children have been associated with respiratory failure and intensive care admission (**N**) (**Level III-2**).
20. Paediatric regional analgesia (peripheral nerve and neuraxial blocks as single injections and continuous catheters) are effective (**Level II**) and safe analgesic techniques in children (**S**) (**Level IV**); continous peripheral nerve catheters have been used in hospital and following discharge, with low secondary failure rates (**N**) (**Level IV**).
21. Ultrasound guidance to assist peripheral block and catheter placement has increased block success (**Level II**) but not impacted the incidence of local anaesthetic systemic toxicity or neurological complications in children; the latter having decreased independently over time (**N**) (**Level IV**).
22. Continuous wound catheter infusions of local anaesthetic are effective (**N**) (**Level II**) and safe analgesic techniques (**N**) (**Level IV**).
23. Caudal local anaesthetic blocks provide effective analgesia for lower abdominal, perineal and lower limb surgery (**Level II**) and have a low incidence of serious complications (**S**) (**Level IV**).
24. Continuous ultrasound-guided caudal injection versus landmark technique increases success of first puncture and lowers risk of vascular puncture and inadvertent subcutaneous injection (**N**) (**Level II**); while permitting real-time visualisation of injectate spread (**N**) (**Level IV**).
25. Sub Tenon block for paediatric ocular surgery achieved longer time to first analgesic administration versus placebo or intravenous opioid (**N**) (**Level II**).
26. Complications of epidural infusions are rare; the rates are slightly higher in neonates and infants versus older children (S) (**Level III-2**).
27. Continuous epidural infusions provide effective postoperative analgesia in children of all ages (**U**) (**Level III-2**).
28. Continuous epidural infusions are safe in children of all ages (**S**) (**Level III-2**) if appropriate doses and equipment are used by experienced practitioners, with adequate monitoring and management of complications (**U**) (**Level IV**).
29. Thoracic epidural, paravertebral catheters, wound catheters and intercostal nerve blocks all provide effective analgesia for pectus excavatum repair surgery, with longer hospital stays in thoracic epidural recipients (**N**) (**Level III-3**).

30. Placement of paediatric regional analgesia (peripheral nerve and neuraxial blocks as single injections and catheters) in children under general anaesthesia is not associated with an increased rate of complications (**S**) (**Level IV**).

☑ An association between urethral fistula formation complicating hypospadias repair and caudal block has not been consistently reported; variation in anatomical presentation and surgical technique are more biologically plausible risk factors (**N**).

☑ Lipid emulsion (20%) has been used in successful resuscitation of paediatric patients (neonates to 18 years) with local anaesthetic systemic toxicity; dosing recommendations are the same as for adults and higher doses have led to adverse effects (**N**).

☑ Dosing practices for peripheral nerve blocks vary and concerningly doses sometimes approach or exceed the accepted safe dose limit; this occurs more commonly in younger children (**N**).

Management of procedural pain in children

Neonates

1. In term neonates, venipuncture is less painful than heel lance (**N**) (**Level I** [Cochrane Review]).
2. Sucrose (**S**) (**Level I** [Cochrane Review]) and non-sucrose sweet solutions (mostly glucose) (**N**) (**Level I** [PRISMA]) reduce pain scores and behavioural response for skin-breaking procedures in neonates.
3. Providing physical comfort measures, including kangaroo care (maternal or alternative skin to skin provider), non-nutritive sucking (alone or combined with sweet-tasting solutions), facilitated tucking (swaddling) or rocking and holding (**N**) reduces pain experienced by term and preterm neonates having skin-breaking procedures (**S**) (**Level I** [Cochrane Review]).
4. Pain from ocular examination for retinopathy of prematurity is reduced by sucrose and non-nutritive sucking (**N**) (**Level I** [Cochrane Review]) and topical local anaesthetic (**N**) (**Level III-1 SR** [Cochrane Review]).
5. Kangaroo care (or skin to skin contact) in neonates reduces the distress of vaccine injection (**N**) (**Level III-1 SR**).
6. Sucrose reduces distress after gastric tube placement in neonates (**N**) (**Level III-1 SR**).

Infants and children

7. Breastfeeding (<2 years of age) reduces pain intensity and crying duration for skin-breaking procedures including vaccine injection compared to positioning, holding by mother, maternal skin to skin contact (<1 months), topical anaesthetics, music therapy, pacifier use (<4 months), placebo, no intervention and/or oral sucrose (**S**) (**Level I** [Cochrane Review]).
8. Non-nutritive sucking reduces pain after needle-related procedures in infants and young children (<3 years) (**N**) (**Level I** [Cochrane Review]).
9. Oral sucrose and glucose reduce cry incidence and duration (**U**) (**Level III-1 SR** [Cochrane Review]**)** and distress (**N**) (**Level III-1 SR**) of vaccine injection in infants.
10. Distraction in infants and young children (<3 years) reduces vaccine injection pain (**N**) (**Level III-1 SR**).

11. Procedural modifications reduced distress of vaccine injection including injection without aspiration (≤18 months), simultaneous injection of multiple vaccines (≤12 months) and injection of most painful vaccine last (≤6 months) (**N**) (**Level III-1 SR**).
12. Topical local anaesthetic reduces distress of vaccine injection in infants (**N**) (**Level III-1 SR**).
13. Parental presence reduces prevaccine injection distress in infants and children (**N**) (**Level III-1 SR**).
14. Parental education before or on vaccination day increases use of evidence-based pain management strategies and reduces distress in infants and children (**N**) (**Level III-1 SR**).
15. Physical interventions including holding by parent (during or after) and non-nutritive sucking in infants (0–4 months) reduces the distress of vaccine injection (**N**) (**Level III-1 SR**).
16. The efficacy of supplemental/expressed breast milk for procedural pain management is unclear (**N**) (**Level III-1 SR**).
17. Needle-free pressure injected lidocaine is quick in onset and reduces pain from subsequent needle-related procedures in infants and children (**N**) (**Level II**).

Children and adolescents

18. EMLA® is an effective topical local anaesthetic for children but amethocaine is superior for reducing needle-insertion pain (**U**) (**Level I** [Cochrane Review]).
19. Topical local anaesthetic application (**U**) **(Level I** [Cochrane Review]), inhalation of nitrous oxide 50–70% or the combination of both (**U**) (**Level I** [PRISMA]) provides effective and safe analgesia for minor procedures in children.
20. Distraction (including with video, toys, music or stories) and hypnosis reduces needle related pain (**S**) and distress (**N**) in children and adolescents (**Level I** [Cochrane Review]).
21. Buzzy® (which combines vibration and cold) (**N**) (**Level I** [PRISMA]) and vibration by other methods (**S**) (**Level III-1 SR**) reduces needle-related procedure pain, including vaccine injection in children.
22. Active and passive music therapy reduces pain and anxiety associated with various needle-related procedures in children (**U**) (**Level I**).
23. Immersive virtual reality reduces pain of medical procedures including wound dressing care and venipuncture (**N**) (**Level III-1 SR** [PRISMA]).
24. Immersive virtual reality for medical procedures in children reduces self-reported pain and anxiety (**N**) (**Level III-1 SR**).
25. Ketamine is effective for paediatric procedural pain management (**Q**) (**Level IV**).
26. Hospital wide initiatives to implement evidence-based standards of care for needle related procedures can improve service delivery and patient satisfaction (**N**) (**Level IV**).

☑ Using combinations of evidence-supported single pain management strategies for painful procedures is strongly recommended (**N**). Non-pharmacological intervention should always be incorporated (**N**).

☑ It is of concern that minor procedures are still undertaken in children, particularly neonates and infants, in the elective and emergency hospital setting with minimal or no pain management intervention (**N**).

- ☑ Inadequate monitoring, lack of adequate resuscitation skills and equipment, and the use of multiple medicine combinations has been associated with major adverse outcomes during paediatric procedural analgesia and sedation (**U**).
- ☑ Pain caused by injection is a barrier to vaccine uptake; thus managing vaccine injection pain has immediate and long term implications for the wellbeing and health of individuals and society (**N**).
- ☑ Based on data from other specific phobias, exposure-based therapy (*in vivo* or imagined) is recommended for children and adolescents (7–17 years) with needle phobia receiving vaccine injections (**N**).
- ☑ Hypnosis requires teaching by a trained professional, but distraction can be readily provided by staff or parents and should be routinely offered in the paediatric setting (**U**).
- ☑ For children and adolescents, sitting upright may reduce procedural pain and distress (**N**).

Acute pain in children with cancer

1. PCA and continuous opioid infusions are equally effective in the treatment of pain in mucositis in children, but opioid consumption and duration of pain is less with PCA (**U**) (**Level I** [Cochrane Review]).
2. Topical local anaesthetic application for children having central venous port access is effective and analgesia is not further improved by oral analgesics (morphine or paracetamol) (**U**) (**Level II**).
3. Self-reported pain scores by children with cancer were higher in intensity compared with nurse-reported pain scores, with variable agreement with parent/carer-reported pain scores (**N**) (**Level III-2 SR**).
4. There is limited evidence that low-level laser therapy reduces the severity of mucositis in children (**U**) (**Level III-2 SR** [PRISMA]).
5. QT interval prolongation with methadone in children with cancer has been reported without complication; the clinical significance is not clear (**N**) (**Level IV**).
6. Poorly managed pain in children during the terminal stages of cancer is associated with higher levels of long term parental grief (**N**) (**Level IV**).
7. Outpatient intravenous PCA opioid has been used to help children in the terminal stages of cancer stay at home (**N**) (**Level IV**).
8. Transdermal fentanyl patch use may be appropriate in opioid tolerant children with cancer (**N**) (**Level IV**).

- ☑ In paediatric cancer pain management, the same therapeutic approaches as in adults are used, although evidence is limited (**U**).
- ☑ The World Health Organization has removed codeine from the management approach to paediatric cancer pain reducing the number of tiers from three to two: with tier one including nonopioid analgesics and adjuvants and tier two including strong opioids; in 2019 the WHO withdrew the reference document, but it remains endorsed by organisations throughout Australia, New Zealand and internationally until it is replaced (**Q**).

☑ Caution must be taken during uptitration of transdermal systems due to the pharmacokinetic profile of transdermal delivery that has slow penetration and delayed uptake from the stratum corneum (**N**).

Other acute pain conditions in children

Management of pain due to trauma and burns in children

1. For paediatric trauma patients in the prehospital setting, frequency of administration of analgesics is low (**N**) (**Level IV SR**) and documentation of pain assessment is variable (**N**) (**Level IV**).
2. Intranasal fentanyl is equivalent to intravenous or intramuscular morphine in reducing pain associated with paediatric fracture presenting to the emergency department (**U**) (**Level II**).
3. Intranasal ketamine (1–2 mg/kg) achieves similar pain reduction to intranasal fentanyl (1.5–2 mcg/kg) for isolated limb fracture pain, but with an increased frequency of minor side effects (eg dizziness, bad taste) (**N**) (**Level II**).
4. The introduction of an intranasal fentanyl protocol for limb injury can reduce the time to first analgesia in the emergency department, compared to intravenous morphine (**N**) (**Level III-3**).
5. Single shot fascia iliaca compartment block is effective in managing femoral fracture pain (**N**) (**Level III-3**).
6. Methoxyflurane, intranasal or intravenous fentanyl and intravenous morphine are effective and commonly used prehospital to manage pain from trauma (**N**) (**Level IV**); intravenous or intranasal ketamine is also an effective analgesic in the prehospital setting (**U**) (**Level IV**).
7. Younger children (<3 years) with an isolated limb injury receive less analgesia in the emergency department than older children (**N**) (**Level IV**).
8. In children and adolescents admitted to hospital with burns, higher morphine doses during admission predict reduced post-traumatic stress symptoms (**N**) (**Level IV**).
9. Pruritus following burn injury in children is common; predictors for pruritus include greater total body surface area of burn and greater number of days since burn injury (**N**) (**Level IV**).

☑ Administration of analgesia by emergency medical services and emergency departments for trauma patients (including those with burns) is strongly recommended as part of the initial resuscitation along with first aid measures such as cooling and dressings for burns and splint application for trauma (**N**).

☑ Gabapentin and pregabalin are used to manage pruritus and neuropathic pain following burn injury in children (**N**).

Paediatric migraine

1. In children (<12 years), effective acute migraine treatments include ibuprofen and triptans (**Q**) (**Level I** [Cochrane]), however there is a significant placebo response rate in this setting.
2. In adolescents (12–17 years), triptans are effective acute migraine treatments, however there is a significant placebo response rate in this setting. One triptan cannot be recommended over another (**Q**) (**Level I** [Cochrane]).

3. Nonpharmacological preventive therapies including relaxation training and cognitive behavioural therapy reduce the frequency and intensity of headache in adolescents for 1 year (**S**) (**Level I** [Cochrane]). Biofeedback also reduces migraine attack duration (**S**) (**Level I**).

☑ Guidelines for the treatment of migraine in children and adolescents recommend environment modification, paracetamol, ibuprofen, naproxen (or other nonselective NSAIDs), dopamine antagonists (if nausea prominent), fluid therapy and triptans (**U**).

☑ Evidence is limited for standard of care second line therapies (single and multiple IV therapies including fluids and antiemetics) and third line therapies (such as IV dihydroergotamine, magnesium, sodium valproate, lidocaine or propofol) for acute childhood migraine (**N**).

☑ The use of psychological interventions and stress management strategies have not been assessed in acute migraine episodes; it must be recognised that many of these skills need to be developed over time (**N**).

Acute abdominal pain in children

1. Probiotics improve pain in children with recurrent abdominal pain versus placebo (**N**) (**Level I** [Cochrane Review]) with no good evidence for positive effect of various pharmacological treatments (**N**) (**Level I** [Cochrane Review]).

2. Cognitive behavioural therapy (CBT) and hypnotherapy reduce pain short term (over 1 to 3 months) in children and adolescents with recurrent abdominal pain (**N**) (**Level I** [Cochrane Review]).

Acute pain associated with haematological disorders in children

Sickle cell disease

1. Hydroxyurea decreases the frequency of acute vaso-occlusive crises, life-threatening complications and hospitalisations in children with sickle cell disease (**S**) (**Level I** [Cochrane Review]).

2. Intravneous or oral magnesium does not reduce pain of vaso-occlusive crises associated with sickle cell crises or length of hospital stay (**N**) (**Level I** [Cochrane Review]).

3. Attention must be paid to acute kidney injury risk in sicker inpatients with sickle cell disease receiving multiple doses of nsNSAID (**N**) (**Level III-3**).

4. Parenteral corticosteroids reduced the duration of severe pain in children with vaso-occlusive crises in sickle cell disease at the expense of more rebound attacks post cessation (**Q**) (**Level II**).

☑ It is standard of care for oral and IV paracetamol, nsNSAIDs and opioids to form part of an individual at home or hospital care plan for children with vaso-occlusive crises. Upon admission this is escalated to parenteral nsNSAID and opioid therapy (**N**).

☑ There is no evidence that fluid replacement therapy reduces pain in children with VOC, although it is common practice (**N**).

☑ The impact on painful vaso-occlusive crises of oxygen supplementation in patients with and without obstructive sleep apnoea and CPAP in patients with obstructive sleep apnoea requires assessment (**N**).

☑ Most children with sickle cell disease are not on opioids for chronic or frequent recurrent pain (while adolescents are, at similar rates to affected adults). In patients with sickle cell disease, postoperative opioid requirements may be higher (**N**).

☑ Adjunctive low-dose ketamine and IV lidocaine infusions reduce pain intensity and opioid requirements in refractory pain of acute vaso-occlusive crisis in children with sickle cell disease (**N**).

Haemophilia

☑ In children with haemophilia, on demand and preventative use of recombinant factor concentrates has improved pain-related quality of life measures. Otherwise the principles of pain management in acute bleeds in affected children and adults involve rest, ice, compression and elevation and stepwise escalation of analgesia. Parents of young affected children need education regarding analgesic medication (**N**).

The overweight or obese child or adolescent

☑ When dosing medication in the overweight or obese child or adolescent, age of the patient, each individual drug and the dose type (initial or maintenance) must be considered (**N**).

☑ Given the barriers to accurate dosing in overweight and obese children, judicious dosing and titration to effect wherever possible is recommended. This requires consideration of both pharmacokinetic and pharmacodynamic factors (**N**).

☑ Young and obese children with history of obstructive sleep apnoea syndrome/sleep-disordered breathing are at higher risk of developing serious opioid-induced ventilatory impairment and death (**U**) (**Level IV**).

Complementary and alternative medicines and therapies in children

1. Hypnosis for needle-related procedural pain (including for cancer-related procedures) reduces pain intensity (**S**) and distress (**N**) versus control (**Level I** [Cochrane Review]).
2. Preventive use of probiotics does not reduce infantile colic incidence, but does reduce crying duration versus placebo (**N**) (**Level I** [Cochrane Review]).
3. The probiotic *Lactobacillus reuteri* reduces cry/fuss time in breastfed infants with colic; there is insufficient evidence in formula fed infants (**N**) (**Level I** [PRISMA]).
4. Oral administration of honey versus control in children reduces pain and analgesic use after tonsillectomy (**N**) (**Level I** [PRISMA]).
5. Perioperative acupuncture (including electroacupuncture) versus control in children having tonsillectomy reduces postoperative pain intensity (in the first 48 h) and analgesic consumption (**N**) (**Level I** [PRISMA]).
6. Acupuncture (invasive or non-invasive) versus control for preterm and term neonates receiving heel lance does not reduce pain intensity (**N**) (**Level I** [PRISMA]).

☑ Complementary and alternative medicines and therapies encompass a wide variety of interventions with common use in the community; complementary medicines and therapies are increasingly used as part of integrative approaches to hospital-based healthcare in the paediatric population (**N**).

☑ The evidence on complementary and alternative medicines and therapies is characterised by small sample sizes and study designs prone to bias and caution is urged in interpreting results. Additionally, the safety and potential drug interactions of many complementary and alternative medicines and therapies have not been adequately assessed (**N**).

1.1.1 | Definition of acute pain

Pain is most commonly described as "*an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage*", (Merskey 1994 **GL**). It should be noted that "*pain is subjective and indicates that each individual learns the application of the word through experiences related to injury in early life, and characterizes the experience as unpleasant, and therefore emotional as well as sensory in nature*" (IASP 2019a **GL**). Chronic pain has gradually emerged as a distinct phenomenon in comparison with acute pain with the IASP currently defining it as *"pain that lasts or recurs for longer than 3 months"* (Treede 2019 **GL**). Although acute pain cannot be precisely distinguished from chronic pain using time-based definitions, for pragmatic purposes recommended definitions continue to be time-based (Kent 2019 **GL**):

"*Acute pain is considered to last up to seven days, with the following qualifications:*

1. *Its duration reflects the mechanism and severity of the underlying inciting event.*
2. *Prolongations from seven to 30 days are common.*
3. *Prolongations beyond the duration of acute pain but not extending past 90 days post onset/-injury are common. This refers to the ill-defined but important period of "subacute" pain that warrants further specification and consideration in future taxonomic, research, and regulatory efforts.*
4. *Our understanding of pain mechanisms is currently insufficient to link these durations to specific physiologic mechanisms*."

This section focuses on the physiology and pathophysiology of pain resulting from nociceptive activity in the sensory nervous system, but also introduces the neurobiology of pain as a beneficial adaptive brain state that responds to and can be altered by psychological factors. A more complete description of the classes of psychological factors that affect the experience of pain is outlined in Section 1.2; for paediatric information se Section 10.1.

1.1.2 | Nociceptive pathways and pain perception

The ability of the somatosensory system to detect noxious and potentially tissue-damaging stimuli (ie nociception) is an important protective feature that involves multiple interacting peripheral and central mechanisms (Sommer 2018 **NR**). In addition to the sensory effects, the perception and experience of pain is multifactorial and will be influenced by genetic, psychological and environmental factors in every individual (Tracey 2019 **NR EH**; Porreca 2017 **NR**; Vardeh 2016 **NR**).

1.1.2.1 | Peripheral nociceptors

The detection of noxious stimuli by peripheral sensory nerve endings (nociceptors) first requires the transduction of noxious stimuli into electrical activity and the conduction of these nociceptive signals in peripheral sensory nerves to the central nervous system (CNS) (Sommer 2018 **NR**; Dubin 2010 **NR**; Woolf 2007 **NR**). Nociceptive primary afferents are widely distributed throughout the body (skin, muscle, joints, viscera, meninges) and comprise both medium-diameter lightly myelinated A-delta fibres and small-diameter, slow-conducting unmyelinated C fibres. Distinct classes of nociceptors are activated by noxious stimuli, which include intense pressure, extreme temperatures (>40 to 45°C or <15°C) and damaging chemicals. The most

prevalent subclass of nociceptor is the C-fibre polymodal type, which responds to mechanical, thermal and chemical stimuli, whereas other subclasses are specialised mechanical, heat or cold nociceptors (Woolf 2007 **NR**).

The physiological properties of nociceptors are determined by the differential expression of a repertoire of transduction molecules (Dubin 2010 **NR**). The particular expression of these transducers determines which modalities are detected by each set of nociceptors. For example, the transient receptor potential (TRP) channel type vanilloid 1 (TRPV1) transduces noxious temperatures from 39–51°C and generates electrical receptor potentials in a class of polymodal C fibres. All nociceptor axons have free terminal endings without anatomically specialised transducers such as the Meissner's corpuscles and Merkel cells used by skin mechanoreceptors. However, it is now known that molecular transducers used by mechanosensitive neurons, such as Piezo1 and Piezo2, are also widely expressed by non-neuronal cells in skin and other organs that can bidirectionally interact with somatosensory terminals including nociceptors (Oetjen 2018 **NR**; Moehring 2018 **NR**). Nociceptors in visceral tissue show differences to those in somatic tissue but are much less well studied. In the viscera, high threshold specific nociceptors are unusual and most mechanosensitive afferents code stimulation in a linear manner, which can reach the noxious range. There is a large proportion of silent nociceptors in viscera, which are unresponsive under basal conditions and respond to heat and chemical stimuli in the presence of inflammation (Grundy 2019 **NR**; Gebhart 2016 **NR**).

Nociceptors may also be classified by their relationship to trophic factors (Denk 2017 **NR**). Some C-fibre nociceptors are dependent on nerve growth factor (NGF) and express tyrosine kinase receptor (TrkA), which is a neurotrophin receptor. Most of these nociceptors also express substance P and calcitonin gene-related peptide (CGRP) and are classed as peptidergic. Another class of C fibres are not peptidergic but have glial cell line-derived neurotrophic factor (GDNF) family receptors (GFRα1, GFRα2; and their co-receptor Ret) and are thereby targets for GDNF or neurturin, respectively**.** Next generation sequencing and transcriptional profiling (by bulk sequencing or single-cell RNA-Seq) has been used for unbiased classification of primary sensory neurons, including nociceptors (Iadorola 2018 **NR**; Emery 2018 **NR**). A large proportion of differentially expressed genes that define classes encode membrane ion channels and receptors that function in nociceptor transduction and transmission (Waxman 2014 **NR**; Gold 2010 **NR**). However, the function of other transcripts identified by this unbiased approach have yet to be determined. This is advancing our understanding and resolving the conflicting alignment between classes previously defined by molecular, neurochemical, developmental and physiological criteria (Gatto 2019 **NR**; Emery 2018 **NR**).

Nociceptor plasticity

Sensitisation is a characteristic of nociceptors (Woolf 2007 **NR**). The phenotypes of the nociceptors change in response to nerve injury and inflammation and are not static. This dynamic neural plasticity lowers the transduction threshold of nociceptors and contributes to primary hyperalgesia, which is defined as abnormal intensity of pain relative to the stimulus (Gold 2010 **NR**; Sandkuhler 2009 **NR**).

Sensitisation is most often produced by chemical signals of tissue damage: such as during infection, inflammation or ischaemia; disruption of cells; degranulation of mast cells; secretions from inflammatory cells; or following induction of enzymes such as cyclooxygenase-2 (COX-2) (Baral 2019 **NR**; Sommer 2018 **NR**; Oetjen 2018 **NR**). A majority of chemical mediators act locally at nociceptor terminals by directly targeting ion channels or indirectly by activating intracellular signalling via calcium-permeable channels (Bourinet 2014 **NR**) or membrane receptors (see Table 1.1). NGF, immune mediators and other chemicals including proteinases, cytokines such as

tumour necrosis factor (TNF) alpha, interleukins, and chemokines such as chemokine (C-C motif) ligand 3 (CC L3) all have an impact on sensitisation of nociceptors (see Table 1.1).

TRPV1 is an example of a nociceptor transducer that contributes to sensitisation in nociceptor terminals. This is achieved when the thermal and chemical sensitivity of TRPV1 is lowered following direct or indirect modulation by local inflammatory mediators or by noxious environmental chemicals such as capsaicin (which causes the perception of heat and pain elicited by chillies) (Henrich 2015 **Level III-1 EH**). Neuropeptides (substance P and CGRP) released from the activated peripheral terminals via peripheral antidromic axonal responses cause neurogenic inflammation by promoting vasodilation and plasma extravasation. This promotes recruitment of serum factors and inflammatory cells at the site of injury (Sousa-Valente 2018 **NR**). Nonsteroidal anti-inflammatory drugs (NSAIDs) modulate peripheral pain by reducing prostaglandin E2 (PGE_2) synthesis from locally induced COX-2. Inflammation also induces changes in protein synthesis in the cell body of neurons in the dorsal root ganglia (DRG) and trigeminal ganglia, and alters the expression and transport of receptors, such as TRPV1 and opioid receptors, to the peripheral nerve terminal (Woolf 2007 **NR**). The latter underlies the peripheral action of opioid agonists in inflamed tissue and could allow nociceptor modulation by immune cells (Stein 2009 **NR**).

Table 1.1 | Examples of receptors and ligands that function in transduction or primary and secondary hyperalgesia of nociceptive primary afferent or spinal cord neurons

	Subtype	Ligand/Stimulus
Ionotropic receptor		
TRP	TRPV1	heat (≥43°C, unsensitised), capsaicin, H^+ (protons)
	TRPV2	heat (≥52°C)
	TRPV3, TRPV4	warm (32 to 39°C)
	TRPA1	environmental irritants (mustard oil, nicotine, formaldehyde, acrolein)
	TRPM8	cool (≤26°C)
acid sensing	ASIC1-4, TRAAK/TREK	H^+ (protons)
glutamate	NMDA, AMPA Kainate, GLurR1-5, NR1-2	glutamate
nicotinic	nACh (multiple subtypes)	acetylcholine
purine	P2X1-6	ATP
serotonin	$5\text{-}HT_3$	5-HT
Metabotropic receptor		
bradykinin	B_I, B_2	bradykinin
cannabinoid	CB_1, CB_2 (TRPs, non-canonical)	anandamide, cannabidiol

	Subtype	Ligand/Stimulus
chemokine	CXCR2,CXCR5, CX3CR1	CXCL1, CXCl13, CCL2 (MCP1), et al.
histamine	H_1	histamine
Interleukin	IL1R, IL-31A/OSMR, et al.	IL-1 alpha, IL-6, IL-31, et al.
LPS	Toll-like receptor 4	lipopolysaccharides
Mas-related GPCRs	MRGPRD, MRGPRA3, MRGPRX1	β-alanine, BAM8-22, other orphan ligands
metabotropic glutamate	$mGLuR_{1,2/3,5}$	glutamate
prostanoids	EP_{1-4} IP	PGE_2 (prostaglandins) PGI_2 (prostacyclin)
proteinase	PAR_{1-4} (TRPs non-canonical)	protease
serotonin	$5\text{-}HT_{1A}$, $5\text{-}HT_{2A,}$ $5\text{-}HT_4$	5-HT (serotonin)
tachykinin	neurokinin-1 (NK_1)	substance P, neurokinin A
tyrosine kinase receptor	TrkA, p75 neurotrophin	NGF (nerve growth factor)
TNR receptor	TNFR1, TNFr2	TNF (tumour necrosis factor)
Pore forming toxins		
haemolysin	α-haemolysin, γ- haemolysin AB	Secreted by gram-positive bacteria (eg *S. aureus*)

Sources: Baral 2019; Sommer 2018; Harding 2018; Oetjen 2018; Gold 2010.

Similarly, NGF increases with inflammation, binds to TrkA, which causes phosphorylation of the TRPV1 and facilitates the sodium channels, which both increase nociceptor activity. In addition, NGF-TrkA complex is transported to the DRG, where it impacts on phenotypic changes resulting in changes to receptors and channels (Denk 2017 **NR**). NGF regulates relative amounts of neuropeptides and the threshold of nociceptors. The number of receptors for NGF (TrkA) is also determined by the functions of the corresponding DRG cells. Visceral primary afferents have a higher proportion of cells containing TrkA compared to somatic primary afferent neurons.

Sodium, potassium, calcium and chloride ion channels also function in nociceptor transduction and transmission. Sodium channels are a prerequisite for conduction of neuronal action potentials to the CNS (Bennett 2019 **NR**). A rapidly inactivating fast sodium current that is blocked by tetrodotoxin is present in all sensory neurons. This is the principal site of action for local anaesthetics but, as the channel is present in all nerve fibres, conduction in sympathetic and motor neurons may also be blocked. Subtypes of slowly activating and inactivating tetrodotoxin-resistant sodium currents are selectively present on nociceptive fibres. Following injury, changes in sodium-channel kinetics and specific alterations in the expression of sodium channels (upregulation or downregulation) contribute to hyperexcitability that occurs in different pain states and may explain part of the mechanism of benefit of systemic local anaesthetics in acute and chronic pain (see Section 4.4.1) . The importance of sodium channels

in pain sensitivity is reflected by the impact of human mutations in the SCN9A gene encoding the $Na_v1.7$ channel (Dib-Hajj 2019 **NR**) (see Section 1.7.1). Loss of function results in insensitivity to pain, whereas gain of function mutations can produce erythromelalgia and other severe pain. These effects are not restricted to sodium channels; functional and expression changes in other classes of calcium, potassium and chloride channels also contribute to nociceptive transmission and processing by nociceptors (Bennett 2019 **NR**).

Medicines that are specific blockers of sodium channel subtypes or cause state-dependent reductions in sodium channel activity are becoming available for evaluation in human clinical trials (Dib-Hajj 2019 **NR**). New ion channel targets are also emerging that, as well as regulators of afferent fibre excitability, include a separate class of ion channels that regulate the transfer of the nociceptive signal (synaptic transmission) from primary afferent fibres to the second-order neurons in the spinal cord (Yekkirala 2017 **NR**).

1.1.2.2 | Nociceptive transmission in the spinal cord

The cell bodies of nociceptive afferents that innervate the trunk, limbs and viscera are found in the DRG, while those innervating the head, oral cavity and neck are in the trigeminal ganglia and project to the brainstem trigeminal nucleus (Dubin 2010 **NR**). The central terminals of C and A-delta fibres convey information to nociceptive-specific areas within laminae I and II of the superficial dorsal horn and to wide dynamic range neurons in lamina V, which encode both innocuous and noxious information (Koch 2018 **NR**; Todd 2010 **NR**). By contrast, large myelinated A-beta fibres transmit light touch or innocuous mechanical stimuli to the deeper laminae III and IV (Moehring 2018 **NR**).

Primary afferent terminals activate dorsal horn neurons by releasing two major classes of neurotransmitter; glutamate as the primary transmitter and neuropeptides such as substance P, CGRP, galanin and somatostatin as cotransmitters (Sandkuhler 2009 **NR**). Depolarisation of the primary afferent terminal results in glutamate release, which activates postsynaptic ionotropic α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA) receptors and rapidly signals information relating to the location and intensity of noxious stimuli. In this “normal mode”, a high-intensity stimulus elicits brief localised pain and the stimulus-response relationship between afferent input and dorsal horn neuron output is predictable and reproducible (Prescott 2014 **NR**; Sandkuhler 2009 **NR**).

Summation of repeated C-fibre inputs results in a progressively more depolarised postsynaptic membrane and removal of the magnesium block from the N-methyl-D-aspartate (NMDA) receptor. This is mediated by glutamate acting on ionotropic (non-NMDA) and metabotropic (mGluR) glutamate receptors, and by substance P acting on neurokinin-1 (NK1) receptors. A progressive increase in action potential output from the dorsal horn cell is seen with each stimulus and this rapid increase in responsiveness during the course of a train of inputs has been termed “wind-up”. Long-term potentiation (LTP) is induced by higher frequency stimuli but the enhanced response outlasts the conditioning stimulus. This mechanism has been implicated in learning and memory in the hippocampus and pain sensitisation in the spinal cord (Sandkuhler 2009 **NR**). Behavioural correlates of these electrophysiological phenomena have been seen in human volunteers as repeated stimuli elicit progressive increases in reported pain (Treede 2016 **NR**).

Intense and ongoing stimuli further increase the excitability of dorsal horn neurons, leading to central sensitisation (Woolf 2014 **NR**; Baron 2013 **NR**; Woolf 2011 **NR**). Increases in intracellular calcium due to influx through the NMDA receptor and release from intracellular stores activate a number of intracellular kinase cascades. Subsequent alterations in ion channel and/or receptor activity and trafficking of additional receptors to the membrane increase the efficacy of synaptic

transmission. As a result of the increased excitability of central nociceptive neurons, their threshold for activation is reduced. In this situation, pain can occur in response to low-intensity previously nonpainful stimuli (ie allodynia) and sensitivity spreads beyond the area of tissue injury (ie secondary hyperalgesia) (Sandkuhler 2009 **NR**). Wind-up, LTP and secondary hyperalgesia may all contribute to central sensitisation and may share some of the same cellular mechanisms but are independent phenomena.

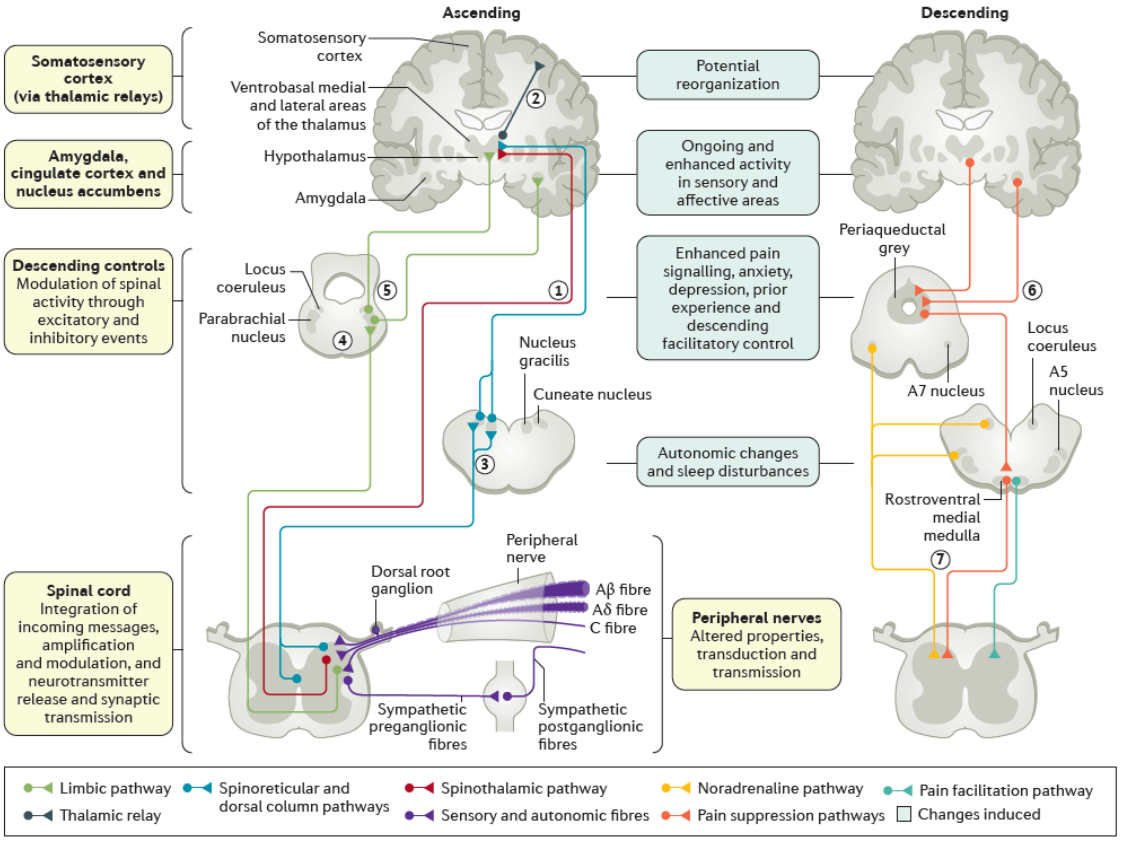
The intracellular changes associated with sensitisation may also activate a number of transcription factors both in DRG and dorsal horn neurons, with resultant changes in gene and protein expression (Ji 2018 **NR**; Simonetti 2013 **NR**). Unique patterns of either upregulation or downregulation of neuropeptides, G-protein coupled receptors, growth factors and their receptors, and many other signalling molecules occur in the spinal cord and DRG in inflammatory, neuropathic and cancer pain. Further elucidation of changes specific to different pain states may allow more accurate targeting of therapy in the future.

In addition to activity in neurons, central neuroinflammation involving surrounding glial and immune cells (including microglia) can also modulate synaptic transmission (Baral 2019 **NR**; Ji 2018 **NR**). Strong evidence has accumulated to suggest glial and neuroimmune mechanisms contribute to sex differences in pain (Mapplebeck 2017 **NR**).

1.1.2.3 | Central projections of nociceptive pathways

Different qualities of the overall pain experience are subserved by five major ascending spinal cord projection pathways; the spinothalamic, spinoreticular, spinomesencephalic, cervicothalamic and spinohypothalamic pathways. The spinothalamic pathway ascends from primary afferent terminals in laminae I and II, via connections in lamina V of the dorsal horn, to the thalamus and then to the somatosensory cortex (Craig 2003 **NR**). This pathway provides information on the sensory-discriminative aspects of pain (ie the site and type of painful stimulus). The spinoreticular and spinomesencephalic (spinoparabrachial) tracts project to the medulla and midbrain and are important for integrating nociceptive information with arousal, homeostatic and autonomic responses as well as projecting to central areas mediating the emotional or affective component of pain (Kobayashi 2012 **NR**; Craig 2009 **NR**; Price 2000 **NR**). Many of the second-order projection neurons in these pathways are superficial dorsal horn lamina I neurons that express the NK1 receptor and are stimulated by peptidergic C-fibre afferents (Todd 2010 **NR**). Other connections include those to cortical areas involved in the affective and motivational components of pain (eg anterior cingulate cortex, insular and prefrontal cortex), projections back to the periaqueductal grey (PAG) region of the midbrain and rostroventromedial medulla (RVM), which are crucial for fight or flight responses and stress-induced analgesia, and projections to the reticular formation that are important for the regulation of descending pathways to the spinal cord. Descending projections from the medullary dorsal reticular nucleus (DRt) are important in facilitating the diffuse noxious inhibitory control (DNIC) (see Figure 1.1) (Treede 2016 **NR**; Ossipov 2010 **NR**; Tracey 2007 **NR**).

Figure 1.1 | The main ascending and descending spinal nociceptive pathways



In the ascending afferent pathways, the sensory components of pain are via the spinothalamic pathway to the ventrobasal medial and lateral areas ①, which then project to the somatosensory cortex allowing for the location and intensity of pain to be perceived ②. The spinal cord also has spinoreticular projections and the dorsal column pathway to the cuneate nucleus and nucleus gracilis ③. Other limbic projections relay in the parabrachial nucleus ④ before contacting the hypothalamus and amygdala, where central autonomic function, fear and anxiety are altered ⑤. Descending efferent pathways from the amygdala and hypothalamus ⑥ drive the periaqueductal grey, the locus coeruleus, A5 and A7 nuclei and the rostroventral medial medulla. These brainstem areas then project to the spinal cord through descending noradrenaline (inhibition via α2 adrenoceptors) and, in neuropathy, there is a loss of this control and increased serotonin descending excitation via 5-HT3 receptors ⑦. The changes induced by peripheral neuropathy on peripheral and central functions are shown.

Reproduced with permission from Colloca 2017.

1.1.2.4 | Descending modulatory pathways

The brain has a remarkable capacity to modulate pain according to the competing demands of physiological, psychological and social factors. The neural contributors to this modulation are complex and only partly elucidated. Best understood is a descending pain-modulatory circuit that projects to the spinal cord and changes the experience of pain by directly or indirectly modulating (inhibiting or facilitating) nociceptive traffic (Ossipov 2010 **NR**). Descending pathways contribute to the modulation of nociceptive transmission in the spinal cord via presynaptic actions on primary afferent fibres, postsynaptic actions on projection neurons or via effects on interneurons within the dorsal horn. Sources include direct corticofugal and indirect (via

modulatory structures such as the PAG) pathways from the cortex and from the hypothalamus, which is important for coordinating autonomic and sensory information. The RVM receives afferent input from brainstem regions (PAG, parabrachial nucleus and nucleus tractus solitarius) as well as direct ascending afferent input from the superficial dorsal horn and is an important site for integration of descending input to the spinal cord (Ossipov 2010 **NR**). The relative balance between descending inhibition and facilitation varies with the type and intensity of the stimulus and also with time following injury (Chen 2019 **NR**). Serotonergic and noradrenergic pathways in the dorsolateral funiculus (DLF) contribute to descending inhibitory effects and serotonergic pathways have been implicated in facilitatory effects (Bannister 2017 **NR**).

Inhibitory modulation occurs within the dorsal horn and can be mediated by non-nociceptive peripheral inputs, local inhibitory gamma-amino butyric acid (GABA) and glycine interneurons, descending bulbospinal projections and higher-order brain function (eg distraction, cognitive input). These inhibitory mechanisms are activated endogenously through neurotransmitters such as endorphins, enkephalins, noradrenaline (norepinephrine) to reduce the excitatory responses to persistent C-fibre activity. Serotonin (5-HT) has been implicated as both pronociceptive and inhibitory (Bannister 2017 **NR**).

Similar mechanisms are the basis of many exogenous analgesic agents (Bannister 2017 **NR**; Ossipov 2010 **NR**; Sandkuhler 2009 **NR**). Thus, analgesia may be achieved by either enhancing inhibition (eg opioids, clonidine, antidepressants) or by reducing excitatory transmission (eg local anaesthetics, ketamine) (Yekkirala 2017 **NR**).

A feature of sensory processing is that not all of the signals received from receptors are perceived. The limited processing capacity of the brain is optimised by prioritising behaviourally relevant signals, while suppressing less important signals. Advances in human functional brain imaging have provided new evidence of how pain perception is shaped by other sensory modalities and attentional or emotional processing by the cerebral cortex and basal forebrain (Wager 2015 **NR**; Carlino 2014 **NR**). The engagement of attention, expectation and reappraisal mechanisms provides for complex cognitive modulation of pain (Bushnell 2013 **NR**; Wiech 2013 **NR**). This is the basis of placebo-induced analgesia (see Section 1.3) and for using psychological interventions to target endogenous pain modulation (Flor 2014 **NR**; Carlino 2014 **NR**).

1.1.3 | Physiological and pathological pain

As discussed in the introduction, pragmatic working clinical definitions of acute and chronic pain continue to be time-based and do not explicitly identify underlying pathophysiology. However, the development of mechanism-based functional classification schemes and identification of clinically useful pain biomarkers continue to be intensively researched (Tracey 2019 **NR**; Vardeh 2016 **NR**).

The basic framework most commonly used addresses heterogeneity of pain by identifying “nociceptive” and “inflammatory” classes of physiological or adaptive pain, together with “neuropathic” and “CNS dysfunctional (nociplastic)” classes of pathological or maladaptive pain (Tracey 2019 **NR**; Kosek 2016 **NR**; Vardeh 2016 **NR**; Woolf 2010 **NR**). Nociceptive and inflammatory pain are considered to be physiological functions of the nociceptive division of the somatosensory nervous system, which monitors the physical state of the body (Sommer 2018 **NR**). It has been understood from the earliest investigations by Sherrington and later landmark studies by Wall and Melzack that this system does not simply locate and measure the intensity of painful sensory stimulation; it also encodes innate aversive reinforcing signals that drive motivational, emotional and cognitive processing in the brain (as described below) (Seymour 2019 **NR**). In humans and other animals, these systems support escape and defensive behaviours that minimise potential lethal tissue damage, as well as coping behaviours that manage recovery from

such damage and avoidance behaviours that use learning signals to minimise the risk of such damage in the future (Seymour 2019 **NR**). This broad functionality can be shown to engage most of the major functional brain subdivisions (Tracey 2019 **NR**). Their basic physiological importance is shown by the unavoidable tissue damage suffered in humans with rare genetic mutations that render them insensitive to pain (Dib-Hajj 2019 **NR**).

Neuropathic pain is defined as "*pain caused by a lesion or disease in the somatosensory nervous system*" (Scholz 2019 **GL**; Jensen 2011 **GL**). The estimated prevalence of neuropathic pain is much higher than commonly thought and in the range of 7–10% of the population (van Hecke 2014 **NR**). Although commonly regarded as a cause of chronic symptoms, neuropathic pain can also present acutely following trauma and surgery. The incidence has been conservatively estimated as 3% of acute pain service (APS) patients (Hayes 2002 **Level IV**). Similarly, acute medical conditions may present with neuropathic pain (Gray 2008 **NR**) (as discussed further in Section 8.1.4). Nerve injury and associated alterations in afferent input or hyperexcitability associated with central pain (eg caused by stroke, spinal cord injury [SCI], multiple sclerosis) can induce structural and functional changes at multiple points in nociceptive pathways with complex long-term psychobiological consequences (Alles 2018 **NR**; Colloca 2017 **NR**; Treede 2016 **NR**; von Hehn 2012 **NR**).

CNS dysfunctional pain syndromes such as migraine, fibromyalgia and chronic pelvic pain show chronicity that often cannot be reliably linked to clinical pathophysiology in the somatosensory system (Woolf 2010 **NR**). Historically, many terms have been used to refer to clinical CNS dysfunctional pain, including "functional pain syndromes", "maldynia", or "neuroplastic" (Mayer 2009 **NR**). The IASP, however, has recently endorsed "nociplastic pain", defined as "*Pain that arises from altered nociception despite no clear evidence of actual or threatened tissue damage causing the activation of peripheral nociceptors or evidence for disease or lesion of the somatosensory system causing the pain*" (IASP 2019a **GL**; Kosek 2016 **NR**). This new term is matched in ICD-11 by the classification '*chronic primary pain'* (Nicholas 2019 **GL**).

When viewed from this perspective, acute pain will most commonly be linked to nociceptive and inflammatory pain but also to less common neuropathic pain. It is clear, however, that the clinical definition will also capture early stages of chronicity that could leadto neuropathic and nociplastic pain in some patients. It is important to recognise that it is currently not possible to identify in advance specific patients who will undergo this transition (Kent 2019 **NR**). The probability of chronic pain developing is subject to the influences of genetic and physiological factors and how these interact with the accumulated psychological and social experiences of pain (Borsook 2018 **NR**; Flor 2014 **NR**; Denk 2014 **NR**). How these combine will determine how individuals experience pain and is also highly likely to determine their underlying resilience in coping with this experience (Bushnell 2013 **NR**; Elman 2013 **NR**) (see Sections 1.2, 1.4 and 1.5).

1.2 | Psychological aspects of acute pain

A new definition of pain has been proposed by the IASP: "*An aversive sensory and emotional experience typically caused by, or resembling that caused by, actual or potential tissue injury*." (IASP 2019b). The revised definition is broadened to include non-verbal presentations (eg in people with communication deficits and animals). A key part of the definition is the recognition that pain is an experience that has emotional and sensory components (ie it is not just a sensation).

This section emphasises several important points:

- Pain is always a personal experience that is influenced to varying degrees by biological, psychological and social factors;
- Pain and nociception are different phenomena – the experience of pain cannot be deduced from activity in sensory pathways;
- Through their life experiences, individuals learn the concept of pain;
- A person's report of an experience as pain should be respected;
- Although pain usually serves an adaptive role, it may have adverse effects on function and social and psychological well-being.

There is a consensus view that pain is an individual, multifactorial experience influenced, among other things, by culture, previous pain experience, beliefs, expectations, mood and ability to cope. Pain may be an indicator of tissue injury but may also be experienced in the absence of, or out of proportion to an identifiable tissue injury, especially when it becomes chronic. The degree of pain and disability experienced in relation to similar tissue injury varies between people; likewise, there is individual variation in response to methods to alleviate pain (Flor 2012 **NR**).

Factors that might contribute to the individual's pain experience include somatic (physical) and psychological factors as well as contextual factors, such as situational and cultural characteristics. Pain expression, which may include facial expressions, body posture, language, vocalisations and avoidance behaviour, partially represents the complexity of the psychological experience but is not equivalent to it (Kunz 2004 **Level III-2 EH**, n=40; Vervoort 2009 **Level IV EH**, n=62). Engel's enunciation (Engel 1997 **NR**) of a biopsychosocial model of illness has provided a framework for considering pain phenomena.

Biopsychosocial models of pain (Turk 1995 **NR**) are based on the proposition that psychobehavioral processes are mediated via neurobiological processes and that they interact. Biological factors are reflected in physiological and neurophysiological changes in the body and psychological factors are reflected in the appraisal and perception of internal physiological phenomena. These appraisals and behavioural responses are, in turn, influenced by social or environmental factors, such as reinforcement contingencies (Flor 2002 **Level III-2**, n=60). At the same time, the model also proposes that psychological and social factors can affect biological processes (eg hormonal/stress responses, endogenous pain regulation) and brain structures associated with the exacerbation and maintenance of pain symptoms (Turk 2018 **NR**).

1.2.1 | Psychological factors

Psychological factors that influence the experience of pain include the processes of attention, other cognitive processes (eg learning, thinking styles, beliefs, mood), behavioural responses and interactions with the person's environment.

Importantly, psychological factors that contribute to the experience and impact of pain (acute or chronic) can be amenable to change and thus influence outcomes for the individual (Nicholas 2011 **NR**).

1.2.1.1 | Attention

In relation to pain, attention is viewed as an active process and the primary mechanism by which nociception accesses awareness and disrupts current activity (Legrain 2012 **NR**; Eccleston 1999 **NR**). The degree to which pain may interrupt attention depends on factors such as the intensity of pain, its novelty, unpredictability, degree of awareness of bodily information, threat value, catastrophic thinking, presence of emotional arousal, environmental demands (such as task difficulty) and emotional significance.

Concepts like somatosensory amplification and hypervigilance have been used to describe the selective attention of patients towards pain to the detriment of more functional activities. These processes have been characterised as attentional bias (ie the preferential allocation of attention to information that is related to pain) and this has been extensively studied in relation to acute, chronic and experimentally induced pain. The most recent meta-analysis of this literature indicated that attentional bias appears to relate more towards the sensory aspects of the pain experience, rather than the emotional content (Todd 2018 **Level IV SR**, 52 studies, n=4,466). It is important to note that these studies may not be completely representative of clinical acute pain (eg postsurgical pain). The role of attentional mechanisms in pain experience and impact is not uniform and terms like "hypervigilance" should not be used loosely as other processes, particularly emotional ones (eg sense of threat), are likely to be involved as well as attention.

1.2.1.2 | Learning processes

The role of learning processes has primarily been studied in laboratory settings with experimentally induced pain. A number of studies using healthy subjects have demonstrated that reports of pain (eg pain severity ratings) can be conditioned by their consequences and this effect can be reflected in measures of associated skin conductance responses, facial activity and cortical responses (Jolliffe 2004, **Level III-2 EH**, n=46; Flor 2002 **Level III-2**, n=60). Taken together, these studies provide support for the thesis that the experience of pain is not solely due to noxious input but that environmental reinforcement contingencies can also influence this experience (see also Section 1.3).

Learning processes have also been implicated in the development and maintenance of chronic pain (Flor 2012 **NR**).

1.2.1.3 | Beliefs and thought processes

Empirical evidence supports a role for "fear of pain" contributing to the development of avoidance responses following pain and injury, which ultimately lead to disability in many people with persisting pain (Leeuw 2007 **NR**). From this perspective, appraisals of internal and external stimuli as threats (eg catastrophising), negative affectivity and anxiety sensitivity can contribute to the development of pain-related fear and, in turn, lead to escape and avoidance behaviours, as well as hypervigilance to internal and external illness information, muscular reactivity, and physical disuse and behavioural changes.

Studies with a range of patient samples have confirmed that thinking styles that are overly pessimistic, ruminative and helpless (eg catastrophic thinking) are frequently associated with more severe acute pain and associated distress, as well as persisting pain.

In patients who underwent anterior cruciate ligament repair, those with high Pain Catastrophising Scale (PCS) scores assessed prior to surgery reported more pain immediately after surgery and when walking at 24 h compared with those with low scores; however there was no difference in analgesic consumption (Pavlin 2005 **Level IV**, n=48). After breast surgery, catastrophising was associated with increased pain intensity and analgesic use (Jacobsen 1996 **Level IV**, n=59) and after abdominal surgery (Granot 2005 **Level IV**, n=38) and Caesarean section with higher pain scores (Strulov 2007 **Level IV**, n=47). Preoperative PCS scores also predicted pain after total knee arthroplasty (TKA) in the postoperative period (Roth 2007 **Level IV**). After a wide range of surgical procedures , the most important predictors of pain severity up to 5 d following surgery were surgical fear and pain catastrophising (beside preoperative pain and expected pain) (Sommer 2010 **Level IV**, n=1,490). In a clinical sample of aged patients, attentional avoidance of emotionally aversive stimuli prior to surgery predicted acute postoperative pain, measured by the consumption of opioids via patient-controlled analgesia (PCA) (Lautenbacher 2011 **Level IV**, n=58). This measure was a better predictor of postoperative pain than depression, anxiety and pain catastrophising. Subsequently, a systematic review of studies of psychological factors associated with acute postsurgical pain confirmed the most significant correlates are: pain catastrophising, expectation of pain, anxiety (state and trait), depression, optimism, negative affect and neuroticism/psychological vulnerability (Sobol-Kwapinska 2016 **Level IV SR** [PRISMA], 53 studies, n=10,749). This meta-analysis suggests that pain catastrophising is the most strongly associated with acute postsurgical pain (r=0.41; 95%CI 0.28 to 0.52) (see also Section 1.4).

A significant association between anxiety or pain catastrophising and the subsequent development of chronic postsurgical pain (CPSP) was reported in a systematic review in 16 of 29 studies (Theunissen 2012 **Level III-2 SR**, 29 studies, n=6,628). Following TKA, a systematic review found catastrophising is the strongest predictor of chronic pain (Lewis 2015 **Level IV SR**, 32 studies, n=29,993). Another systematic review found patients with acute and subacute back pain with high levels of catastrophising complained of more pain and disability at 6 mth and more disability at 1 y than those with low levels (Wertli 2014a **Level III-2 SR**, 16 studies, n unspecified).

High fear avoidance beliefs in patients with back pain of <6 mth duration are associated with poor outcomes, which may be improved by treatment approaches aimed at fear avoidance (Wertli 2014b **Level I** [PRISMA], 17 RCTs, n=1,153). Early postoperative fear of movement also predicted pain, disability and physical health 6 mth after spinal surgery for degenerative conditions (Archer 2014 **Level III-2**, n=141).

1.2.1.4 | Depression and anxiety

Anxiety and depression have repeatedly been found to contribute to the experience and impact of both acute and chronic pain.

Significant preoperative predictors of poor postoperative pain control included younger age (OR 1.18; 95%CI 1.05 to 1.3) (14 studies), female sex (OR 1.29; 95%CI 1.17 to 1.43) (20 studies), smoking (OR 1.33; 95%CI 1.09 to 1.61) (9 studies), history of depressive symptoms (OR 1.71; 95%CI 1.32 to 2.22) (8 studies), history of anxiety symptoms (OR 1.22; 95%CI 1.09 to 1.36) (10 studies), sleep difficulties (OR 2.32; 95%CI 1.46 to 3.69) (2 studies), higher body mass index (OR 1.02; 95%CI 1.01 to 1.03) (2 studies), presence of preoperative pain (OR 1.21; 95%CI 1.10 to 1.32) (13 studies) and use of preoperative analgesia (OR 1.54; 95%CI 1.18 to 2.03) (6 studies) (Yang 2019 **Level IV SR** [PRISMA], 33 studies, n=53,362). Interestingly, pain catastrophising, American Society of Anesthesiologists (ASA) status, chronic pain, marital status, socioeconomic status, education, surgical history, preoperative pressure pain tolerance and orthopaedic surgery (vs abdominal surgery) were not associated with increased odds of poor pain control.

Anxiety is one of the most significant predictive factors (in addition to pre-existing pain, age and type of surgery) for the severity of postoperative pain (Ip 2009 **Level IV SR**, 48 studies, n=23,037). Psychological distress (besides type of surgery and age) is the most significant predictor of postoperative analgesic consumption, not sex as is commonly believed.

Among other factors, preoperative anxiety predicted pain intensity 48 h after hysterectomy for benign conditions (Pinto 2012 **Level IV**, n=203). Subsequent multivariable analysis revealed that pain catastrophising acted as a full mediator between presurgical anxiety and postsurgical pain intensity. In the late phase after leg injury, anxiety has the only significant relationship to pain (Castillo 2013 **Level IV**, n=545). Anxiety predicted pain over all time periods: 3 to 6 mth (standardised regression weights [SRW] 0.11), 6 to 12 mth (SRW 0.14) and 12 to 24 mth (SRW 0.18).

In opioid-tolerant patients, the anxiety and autonomic arousal associated with withdrawal (Tetrault 2008 **NR**) may also have an impact on acute pain experience and report (see Section 9.7 for further details).

There is a consistent association between chronic postsurgical pain and depression as well as psychological vulnerability and stress (Hinrichs-Rocker 2009 **Level IV**, 50 studies, n≈25,000). Similarly, there is a strong relationship between persistent knee pain and depression (with higher levels of knee pain being positively related to higher levels of depression) but not with anxiety and poor mental health in general (Phyomaung 2014 **Level IV SR**, 16 studies, n=15,113).

1.2.1.5 | Implications

The presence of modifiable psychological factors, especially anxiety, catastrophising and depression, should be considered in acute pain settings and, if identified, should be targeted by treatment. The results of research evaluating psychological interventions for these factors are considered elsewhere (see Section 7.1). These psychological contributors to higher pain levels and interference in daily activities are not universal and there is considerable variability between individuals.

1.2.2 | Patient-controlled analgesia

In general, anxiety seems to be the most important psychological variable that affects PCA bolus use. Preoperative anxiety correlates with increased postoperative pain intensity, the number of PCA demands made by the patient (often "unsuccessful" presses during the lockout interval), degree of dissatisfaction with PCA and lower self-reports of quality of analgesia (Thomas 1995 **Level III-1**, n=110; De Cosmo 2008 **Level IV**, n=80; Hsu 2005 **Level IV**, n=40; Ozalp 2003 **Level IV**, n=99; Brandner 2002 **Level IV**, n=71; Perry 1994 **Level IV**, n=99; Jamison 1993 **Level IV**, n=68). Another study designed to look at predictors of PCA demands made during the lockout interval also found that anxiety and negative affect positively predicted unsuccessful PCA demands and postoperative pain, as did preoperative intrusive thoughts and avoidant behaviours about the impending surgery (Katz 2008a **Level IV**, n=117).

Evidence regarding PCA opioid consumption and psychological variables is however contradictory, with some studies showing no change (Jamison 1993 **Level IV**, n=68; Gil 1992 **Level IV**, n=50; Gil 1990 **Level IV**, n=80) and others showing an increase in analgesia demands (Katz 2008a **Level IV**, n=117; De Cosmo 2008 **Level IV**, n=80; Ozalp 2003 **Level IV**, n=99).

In a study looking at the effect of a number of psychological factors on both pain and IV morphine use (by PCA) in the immediate postoperative period, and on pain 4 wk after surgery, preoperative self-distraction and coping positively predicted postoperative pain levels and morphine consumption; emotional support and religious-based coping positively predicted PCA-morphine consumption; and preoperative distress, behavioural disengagement, emotional

support, and religious-based coping also positively predicted pain levels 4 wk after surgery (Cohen 2005 **Level IV**, n=122).

There was no relationship between locus of control and postoperative pain intensity, satisfaction with PCA or PCA dose-demand ratio (Brandner 2002 **Level IV**, n=71). Preoperative depression was associated with increased pain intensity, opioid requirements, PCA demands and degree of dissatisfaction (Hsu 2005 **Level IV**, n=40; Ozalp 2003 **Level IV**, n=99) (for further details on PCA see also Section 6.0).

KEY MESSAGES

1. High pain-related fear avoidance beliefs in patients with back pain of less than 6 months duration are associated with poor outcomes, which may be improved by treatment approaches aimed at fear avoidance (**U**) (**Level I** [PRISMA]).
2. There is a significant association between high levels of catastrophising in acute and subacute back pain and pain and disability at later points of time (**U**) (**Level III-2 SR**).
3. Psychological factors associated with poor postoperative pain control are in particular anxiety (state and trait) and catastrophising, but also expectation of pain, depression, negative affect and neuroticism/psychological vulnerability (**S**) (**Level IV SR** [PRISMA]).
4. There is significant association between anxiety, pain catastrophising (**U**) (**Level III-2 SR**), depression, psychological vulnerability and stress (**U**) (**Level IV SR**) and the subsequent development of chronic postsurgical pain.
5. Preoperative anxiety and depression are associated with an increased number of PCA demands and dissatisfaction with PCA (**U**) (**Level IV**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Pain is an individual, multifactorial experience influenced by culture, previous pain events, beliefs, mood and ability to cope (**U**).

1.3 | Placebo and nocebo effects in acute pain

The study of placebo is directly relevant to the field of pain management, as it provides further understanding of the mind–brain interaction in the modulation of pain and is a core element of routine clinical management (Finniss 2010 **NR**).

The term "placebo", originally defined as an inert substance having therapeutic response, has been used in the medical literature for over 200 y. Only in the last 50 y, however, has interest grown in responses to placebo administration. The first major systematic review of the topic showed a placebo effect for many interventions but particularly for those interventions aimed at analgesia (Beecher 1955 **Level I**, 15 RCTs, n=1,082). The early studies included in this systematic review of response to placebo were mainly studies of placebo vs active medicine or intervention alone without a control no-treatment group (nonplacebo group).

Placebo effects are psychobiological effects that are attributable to the psychosocial context (or treatment ritual) surrounding the patient. Importantly, these genuine effects must be distinguished from other causes of improvement following administration of a placebo (placebo responses), such as spontaneous remission, regression to the mean and the natural history of acute pain (Price 2008 **NR**). Defining placebo and placebo effects has been difficult, primarily due to the traditional definition, which uses the word "inert", therefore theoretically rendering it as being unable to have any power to elicit an effect (Moerman 2002 **NR**). Recent reconceptualisations of placebo effects have emphasised several key points which are highly relevant to modern pain management practice (Finniss 2010 **NR**; Miller 2008 **NR**).

- Placebo responses refer to all health changes following administration of an inert agent (including natural history and regression to the mean) (Evers 2018 **NR**).
- Placebo effects are changes attributable to specific psychobiological mechanisms, whether a traditional placebo is given or as part of a routine clinical interaction (Evers 2018 **NR**).
- The key aspect of placebo administration is the act of simulating a treatment context or ritual, regardless of the content of the placebo.
- Routine clinical care occurs in a rich therapeutic context and, on this basis, placebo effects exist in everyday practice even though no traditional placebo is given. The overall outcome of a treatment is related to both the treatment itself and the context in which it is given (the component attributable to placebo effects).

The term "nocebo" has been used to express the opposite (negative) response following placebo administration, particularly in relation to development of adverse effects from interventions or, in the case of painful stimuli, with an increased pain response expressed. Nocebo studies in pain show moderate to large nocebo effects of high variability (Petersen 2014 **Level I** [PRISMA], 10 RCTs, n=619). The results are similar to those seen for placebo effects; combinations of verbal suggestions and conditioning (see below) are more effective than verbal suggestions alone. The authors suggest that these results demonstrate "*the importance of minimising nocebo effects in clinical practice*".

1.3.1 | Mechanisms

The study of placebo mechanisms has traditionally been divided into psychological and neurobiological categories, although it is the interplay between the two that is the key to the topic area.

1.3.1.1 | Psychological mechanisms

There are many psychological mechanisms of placebo effects proposed, including expectation, conditioning, learning, reward and anxiety reduction (Price 2008 **NR**).

Expectancy

Expectancy has been one of the most studied psychological mechanisms and relates to patient expectations of a future response. Expectancy can result in increased pain response to nociceptive stimuli as well as a placebo response to an analgesic intervention (Atlas 2012 **NR**). It has been associated with placebo effects in studies, where verbal cue ranges from a simple instruction "*this is a powerful painkiller*" (Price 1999 **Level II**, n=40, JS 4) to the use of conditioning protocols to maximise expectancy (Voudouris 1989 **Level II**, n=20, JS 4; Voudouris 1990 **Level III-1**). Furthermore, a "graded" effect can be seen in studies with variable levels of expectancy (such as the classic "double-blind" instruction, which carries a 50% uncertainty) to more certain information about treatment expectations "*the drug I will give you is a powerful painkiller*" (Vase 2003 **Level II**, n=13, JS 4; Verne 2003 **Level II**, n=10, JS 4; Pollo 2001 **Level II**, n=38, JS 3). More recently, in the setting of chronic low back pain, expectancies were associated with duration and stability of placebo effects following diagnostic injections (Finniss 2019 **Level II**, n=107, JS 5). This underscores the dynamic nature of the construct and emphasises the role of repeated expectancy assessment and modulation over the duration of a healthcare encounter.

Treatment expectations are also involved in studies of the open-hidden paradigm (Finniss 2010 **NR**). Giving a treatment "hidden", without the patient's knowledge (eg by a computerised pump behind a curtain) and comparing the effects when the same treatment is given "open" (in the usual therapeutic context with a health professional present) has shown that open administration of a range of analgesics is, by far, more effective than hidden administration. This approach permits measurement of the placebo effect as "*the difference in effect between the open and hidden administration*". An example of such a trial compared the efficacy of a remifentanil infusion (0.8 ng/mL effect site concentration) on experimental pain in volunteers under three conditions (Bingel 2011 **Level III-3 EH**):

- without expectation of analgesia (hidden administration);
- with expectancy of a positive analgesic effect (open administration by a clinician); and
- with negative expectancy of analgesia (claimed discontinuation of analgesic infusion while infusion continued).

The pain relief achieved by hidden administration of remifentanil was more than doubled by the open administration and completely negated by the claimed discontinuation of the infusion. Functional MRI (fMRI) showed that, during positive expectancy, activity in the endogenous pain modulatory system was increased, while negative expectancy increased activity in the hippocampus.

These findings and the results of other groups suggest that RCTs comparing an analgesic with a placebo may underestimate the efficacy of the analgesic (Lund 2014 **Level II EH**, n=48 [cross over], JS 5). The hypothesis that placebo effect and drug effect are additive, upon which calculation of efficacy is based, is most likely flawed. This is particularly true when the placebo effect is large. Expectations influence placebo and nocebo response to acute pain independently from personality factors (Corsi 2017 **Level III-1 EH**)

In conclusion, expectancy is a powerful determinant of placebo response, with only minor changes in the way information is delivered to the patient having the ability to significantly alter expectancy and the magnitude of the placebo effects.

Classical conditioning

Classical conditioning is a learning phenomenon whereby repeated associations between a neutral stimulus and an active treatment (unconditioned stimulus) can result in the ability of the neutral stimulus itself being able to elicit an effect similar to that of the unconditioned stimulus (Finniss 2010 **NR**). Typically, an opioid analgesic is given on repeated occasions and then replaced with a placebo-treatment simulation. These phenomena have been demonstrated in animals (Pacheco-Lopez 2006 **BS**) and in humans (Voudouris 1989 **Level II EH**, n=20, JS 4; Voudouris 1990 **Level III-1 EH**). In a similar way, treatment history can influence the efficacy of a subsequent treatment (Kessner 2014 **Level III-2 EH**). In an experimental setting, induced negative experience with a first treatment resulted in reduced response to a second analgesic treatment; the size of the effect was modulated by psychological trait variables such as anxiety, depression and locus of control. There is evidence that social or observational learning may also be a determinant of placebo effects (Colloca 2006 **Level III-1 EH**). For example, placebo effects were larger in subjects who had higher empathy after witnessing another volunteer in pain (Colloca 2009 **Level II EH**, n=48, JS 2).

1.3.1.2 | Neurobiological mechanisms

Studies into placebo analgesia have provided a substantial component of the knowledge about placebo mechanisms, although it is now known that there are multiple placebo effects that operate across many different medical conditions (Benedetti 2008 **NR**).

At a biochemical level, pioneering studies have shown that placebo effects in acute pain are either completely or in part mediated by endogenous opioids, by virtue of their reversibility with naloxone (Benedetti 1995 **Level II EH**, n=47, JS 3; Levine 1978 **Level II EH**, n=93, JS 3). The role of cholecystokinin (CCK) was demonstrated through the potentiation of placebo effects using a CCK antagonist (proglumide) (Benedetti 1995 **Level II EH**, n=93, JS 3). Interestingly, CCK has also been shown to be responsible for nocebo effects and this suggests that anxiety and panic mechanisms (also associated with CCK release) may be activated (Benedetti 2007 **NR**).

Using both conditioning and expectancy manipulations with the administration of an opioid analgesic, the resulting placebo effect was mediated by endogenous opioids (Amanzio 1999 **Level II EH**, n=229, JS 3). In contrast, in patients who received a nonopioid analgesic during conditioning, the placebo effect was not reversed by naloxone. These findings are a powerful demonstration that there is not one placebo effect but many. One mechanism for this nonopioid-mediated placebo analgesia was found to be the endogenous cannabinoid system (cannabinoid type 1 [CB_1] receptor) (Benedetti 2011 **Level III-1 EH**).

The neuroanatomy of placebo analgesic effects has been partially unravelled. A positive emission tomography (PET) study demonstrated similar brain changes to placebo as seen with opioid administration (Petrovic 2002 **Level III-2 EH**). Further PET and fMRI studies have supported the involvement of key regions of the brain associated with opioid analgesia (Zubieta 2005 **Level III-3 EH**), including subcortical (Bingel 2006 **Level III-2 EH**) and spinal cord mechanisms (Eippert 2009 **Level III-1 EH**). Taken together, these studies show growing neurobiological evidence of placebo-induced brain and spinal cord modulation of pain, although much more research is needed in this area.

A meta-analysis of 25 neuroimaging studies identified that placebo analgesia and expectancy-based pain modulation resulted in reductions of activity in brain regions involved in pain processing (eg the dorsal anterior cingulate, thalamus and insula) (Atlas 2014 **Level IV EH SR**). Other regions with reduced activity were the amygdala and the striatum; as these are related to affect and valuation, placebo effects involve these components too. In addition, regions such as the prefrontal cortex, the midbrain surrounding the PAG and rostral anterior cingulate showed increased activity with expectations for pain reduction.

There is a link between polymorphisms in the dopamine, opioid and endocannabinoid genes and response to placebo, demonstrating potential genetic determinants of placebo effects (Colloca 2019 **Level III-2 EH**, n=160).

1.3.2 | Clinical findings

Many meta-analyses include studies that also have a control nonplacebo/nocebo group. One of these reveals a relatively small placebo effect size for all clinical conditions (60 assessed) (Hrobjartsson 2010 **Level I** [Cochrane], 234 RCTs, n unspecified), but did not consider nocebo. The majority of studies measured continuous outcomes (158 RCTs, n=10,525) but the results are also consistent in those assessing binary outcomes (44 RCTs, n=6,041). In the studies with continuous outcomes, there is an effect of placebo treatment (SMD -0.23; 95%CI -0.28 to -0.17) (158 RCTs, n=10,525), which is larger for patient-reported (SMD -0.26; 95%CI -0.32 to -0.19) (109 RCTs, n=8,000) than for observer-reported outcomes (SMD -0.13; 95%CI -0.24 to -0.02) (49 RCTs, n=2,513). Overall, larger placebo effects are seen with physical placebo interventions (eg acupuncture), patient-involved outcomes, smaller trials and trials that did not inform patients about the possible placebo intervention.

Importantly, trials aimed at studying placebo effects (rather than assessing responses in placebo-control groups) demonstrate larger placebo effects, particularly in the case of analgesia (Vase 2002 **Level I**, 37 RCTs, n=2,298). Effect sizes can be five times higher in these studies than in analysis of placebo effects on control groups, demonstrating an important difference when understanding placebo effects in clinical trials (where instructions are uncertain and the context does not replicate routine clinical care) (Vase 2009 **Level I** [QUOROM], 24 RCTs, n=602). Consistently positive but highly variable placebo responses are obvious in studies involving analgesia specifically (pooled SMD -0.28; 95%CI -0.36 to -0.19) (60 RCTs [continuous outcome, pain], n=4,154) with a wide range of response in the individual trials from around SMD -1.0 to 0.5. This variability is also seen in targeted studies on placebo (Vase 2009 **Level I** [QUOROM], 24 RCTs, n=602).

1.3.3 | Clinical Implications

The clinical implications of placebo effects are widespread and there is much more research needed to understand how placebo effects operate and how they can be manipulated in clinical practice. However, the notion that placebo effects (and therefore mechanisms) may be a component of routine pain management practice is highly important (Klinger 2014 **NR**; Finniss 2009 **NR**). If one can study how psychosocial factors alter the patient's nociception and the experience of pain (by running experiments in which placebos are given), this has direct implications for clinical care where, even though no placebo is given, placebo effects are present.

In recent times, the ethical debate has shifted somewhat as the concept of placebo is better understood. It is widely accepted that placebos should not be administered in a deceptive manner (Finniss 2010 **NR**; Brody 1982 **NR**). However, there are not the same ethical problems associated with harnessing the placebo effects that coexist with routine "active" treatments, as the outcome of a treatment is attributable to both the treatment itself and the specific context in which it was given (the placebo component). An applied example is that of the PSYHEART trial, where a specific pre-treatment intervention addressing patients expectations pre-cardiac surgery resulted in significant reductions in biological markers (endocrine and immune markers of stress), reduced disability and improved quality of life at 6 mth post-surgery (Rief 2017 **Level II**, n=124, JS 5).

It is suggested that, in a therapeutic interaction, the placebo effect can be clinically utilised by enhancing expectations and using learning components (Klinger 2014 **NR**). Practical examples of this are listed below.

To enhance expectations:

- Assess and manage expectations over the entire time course of a treatment;
- Emphasise positive effects of medicines;
- Avoid stressing adverse effects;
- Explain effects and mechanisms of action of medicines;
- Interact personally with the patient;
- Do not rely only on written handouts; and
- Avoid unrealistic expectations.

To enhance learning components:

- Administer analgesics in an open manner;
- Connect the administration to positive internal states and external conditions;
- Combine analgesics with other pain-relieving approaches, preferably with time-contingent administration of analgesics; and
- Reinforce positive and minimise negative experiences.

KEY MESSAGES

1. Responses to placebo across all clinical conditions are small but consistently positive. They are more prominent, although highly variable in magnitude, in studies of pain (**U**) (**Level I** [Cochrane Review]).
2. Nocebo effects in studies of pain are of moderate to large size and of high variability (**U**) (**Level I** [PRISMA]).
3. Trials aimed at studying placebo effects demonstrate larger placebo effects than those assessing responses in placebo-control groups (**U**) (**Level I** [QUOROM]).
4. Analgesic placebo effects are based upon multiple neurobiological mechanisms, including involvement of endogenous opioid, cholecystokinin (**U**) (**Level II**), endogenous cannabinoid systems (**U**)(**Level III-1**) and genotype (**N**) (**Level III-2**).
5. Analgesic placebo effects are based upon multiple psychological determinants including expectancy, classical conditioning and social and observational learning (**S**) (**Level II**).
6. Placebo and nocebo effects have significant influence on the efficacy of analgesics (**U**) (**Level II**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Placebo effects are the consequence of the psychosocial context (or treatment ritual) on the patient's mind, brain and body (**U**).

☑ Placebo effects occur in routine clinical care even when no traditional placebo is given. The outcome of a treatment is attributable to both the treatment itself and the contextual (or placebo) component (**U**).

☑ Nocebo effects occur in routine clinical care and are seen as an increased pain response to a painful stimulus or the development of adverse effects not caused by, or separate from, the intervention (**U**).

☑ Ethical harnessing of placebo and minimisation of nocebo effects will improve response to clinical management interventions (**U**)

1.4 | Progression of acute to chronic pain

Chronic pain is common in the community and is moderate to severe in intensity in approximately 20% of the population (Kennedy 2014 **Level IV**, n≈39,400,000 [chronic pain sufferers]). This inevitably leads to significant personal and economic cost (Breivik 2006 **Level IV**, n=46,394; Deloitte Access Economics 2019 **NR**). Episodes of acute pain may result in chronic pain with subsequent impact on quality of life, employment and mental health (Steyaert 2012 **NR**; Lavand'homme 2011 **NR**; McGreevy 2011 **NR**). The prediction and prevention of transition to chronic pain may therefore convey health and economic benefits (see also Section 3.3).

The 11th revision of the International Classification of Diseases (ICD-11) defines chronic postsurgical pain (CPSP) as pain developing or increasing in intensity after a surgical procedure, in the area of the surgery, persisting beyond the healing process (ie at least 3 mth) and not better explained by another cause such as infection, malignancy, or a pre-existing pain condition (Schug 2019 **GL**).

CPSP is common and although often mild, may be of sufficient severity to interfere with function and quality of life in 1 to 10% of cases (De Kock 2009 **Level IV**). The currently accepted prevalence of CPSP is shown below, however some studies suggest the prevalence may be lower than previously thought (see Table 1.2) (Chan 2016 **Level II**, n=2,924, JS 5; Fletcher 2015 **Level IV**, n=3,120).

CPSP often has identifiable neuropathic characteristics, although this is procedure specific, and is often poorly responsive to opioids (Chan 2011 **Level II**, n=423, JS 5; Wylde 2011 **Level IV**, n=1,334; Haroutiunian 2013 **NR**; Macrae 2008 **NR**; Kehlet 2006 **NR**). The lack of efficacy of opioids for treating CPSP is one factor contributing to the current prescription opioid crisis (Neuman 2019 **NR**; Hollmann 2019 **NR**) (see also Sections 1.4.3, 8.13 and 9.7).

Other well-characterised acute pain events may also lead to chronic pain, such as post-traumatic pain (see below and Section 8.1), acute back pain (see Section 8.7) and herpes zoster (see Section 8.6.2). Although CPSP tends to be associated with major surgery, involving significant acute pain, nerve injury and inflammation, it may also occur following minor operations. The surgical drive towards minimally invasive surgery has reduced acute postsurgical pain but has had a limited effect on the incidence of CPSP (Roth 2018 **Level IV**, n=1,996; Lavand'homme 2017 **NR**).

This section will focus primarily on CPSP, although the underlying mechanisms and risk factors are also relevant to the nonsurgical conditions mentioned above.

1.4.1 | Epidemiology of chronic postsurgical pain

There is a high prevalence of CPSP and chronic pain following trauma; 22.5% of 5,130 patients attending chronic pain clinics in North Britain cited surgery as a cause for their pain and 18.7% felt that trauma was the primary cause (Crombie 1998 **Level IV**, n=5,130). As chronic pain is very common in the population and only a small percentage of people with chronic pain attend pain clinics, data obtained from clinics may not accurately reflect the scale of the problem in the community. A randomised population survey from Portugal found that only 6% of those identified with chronic pain felt that it was due to surgery (Azevedo 2012 **Level IV**, n=2,213). In contrast, a Norwegian population-based study found 40.4% prevalence of pain in the anatomical region of surgery 3 mth to 3 y later (Johansen 2012 **Level IV**, n=2,043). In 18.3% (n=373), the pain was moderate to severe. The prevalence of moderate to severe pain was reduced to 10.5% by excluding all respondents with the same pain before surgery and to 6.2% by excluding all respondents with any pain before surgery. Factors associated with CPSP were sensory abnormalities in the area of surgery (hyperaesthesia [OR 6.27; 95%CI 4.43 to 8.86] or hypoaesthesia [OR 2.68; 95%CI 1.05 to 3.50]) and psychological distress (OR 1.69; 95%CI 1.22 to 2.36).

Chronic pain following trauma is common and approximately 70% of patients without prior pain reported significant pain 6 mth following injury in one UK study (Rockett 2019 **Level II**, n=64, JS 5). Preceding studies found similar high rates of 46% to 85% of polytrauma survivors with subsequent chronic pain (Gross 2011 **Level IV**, n=229) and 72% of some pain in the last 24 h at 1 y after serious trauma (Holmes 2010 **Level III-2**, n=290).

Less is known about CPSP in the paediatric population, but it has been estimated that 20% of children experience CPSP 1 y after spinal and mixed major surgery (Rabbitts 2017 **Level IV SR**, n=628; (Williams 2017 **NR**).

The incidence of CPSP varies with the type of operation and it is particularly common where nerve trauma is inevitable (eg amputation) or where the surgical field is richly innervated (eg chest wall) (see Table 1.2) (Wylde 2011 **Level IV**, n=1,294; Macrae 2008 **NR**; Kehlet 2006 **NR**). In a prospective cross-sectional study at a university-affiliated hospital and level 1 trauma centre, 14.8% of patients described CPSP, in particular those after trauma and major orthopaedic surgery (Simanski 2014 **Level IV**, n=3,020). A similar study, focussing on neuropathic CPSP only following two procedure types, identified an incidence of 3.2% for laparoscopic herniorrhaphy vs 37.1% for breast cancer surgery at 6 mth after surgery (Duale 2014 **Level IV**, n=3,112). Overall, these data support the high incidence of CPSP and the frequent linkage of CPSP to nerve injury.

Table 1.2 | Incidence of chronic pain after surgery

Type of surgery	Any CPSP (%)	Severe CPSP (%)	Neuropathic pain (proportion)*
Abdominal surgery (visceral)	17-21%	Not reported	Not reported
Amputation	30-85%	5-10%	80%
Caesarean section	6-55%	5-10%	50%
Cholecystectomy	3-50%	Not reported	Not reported
Craniotomy	7-30%	25%	Not reported
Dental surgery	5-13%	Not reported	Not reported
Hip arthroplasty	27%	6%	1-2%
Inguinal herniotomy	5-63%	2-4%	80%
Knee arthroplasty	13-44%	15%	6%
Melanoma resection	9%	Not reported	Not reported
Mastectomy	11-57%	5-10%	65%
Sternotomy (CABG)	30-50%	4-28%	Not reported
Thoracotomy	5-65%	10%	45%
Vasectomy	0-37%	Not reported	Not reported

*CABG-Coronary artery bypass graft surgery; * assessed by screening questionnaires in most studies. Adapted from Glare 2019; Schug 2017.*

1.4.2 | Characteristics of chronic postsurgical pain

Efforts are now being made to standardise outcome measures to characterise CPSP in future RCTs and epidemiological studies (Wylde 2014 **Level IV**, n=1,294; VanDenKerkhof 2013 **GL**). CPSP may persist as a continuum from acute postsurgical pain or it may occur following a pain-free interval. CPSP may occur in the skin or deep tissues of the region of surgery, it may be referred to characteristic areas due to viscerosomatic convergence or be related to the course of a nerve injured by surgery.

A significant proportion of patients with CPSP demonstrate sensory abnormalities, suggesting that CPSP often has a neuropathic component (Johansen 2016 **Level IV**, n=81; Aasvang 2008 **Level IV**, n=46). The incidence of acute neuropathic pain has been reported as 1 to 3%, based on patients referred to an APS, primarily after surgery or trauma (Hayes 2002 **Level IV**). The majority of these patients had persistent pain at 12 mth, suggesting that acute neuropathic pain is a risk factor for chronic pain. These qualitative results were confirmed in a subsequent study (Beloeil 2017 **Level III-2**, n=593). Using a screening tool (DN-4), acute neuropathic pain was identified in 5.6% (95%CI 3.6 to 8.3) on the day of surgery and in 12.9% (95%CI 9.7 to 16.7) on POD 1. Postsurgical neuropathic pain was identified in phone follow-up 2 mth postsurgery in 33.3% of patients; acute neuropathic pain was a risk factor for its development (OR 4.2; 95%CI 2.2 to 8.1). Similarly, immediately after thoracotomy or video-assisted thoracic surgery (VATS), 8% of patients scored positively on another screening tool for neuropathic pain (LANSS) and 22% 3 mth later; again acute neuropathic pain was identified as a risk factor for chronic neuropathic pain (RR 3.5; 95%CI 1.7 to 7.2) (Searle 2009b **Level III-2**, n=100). Following VATS, sensory changes suggestive of nerve injury were demonstrated in most patients but there was no difference in sensory abnormalities or measures of central sensitisation between patients with and without CPSP (Wildgaard 2012 **Level IV**). Similarly, changes in sensory thresholds (warmth detection and heat pain) were demonstrated in most pain-free patients following open inguinal herniorrhaphy (Aasvang 2010b **Level IV**). This suggests that, although nerve injury is frequently associated with CPSP, such injury does not inevitably lead to chronic pain. It should be recognised however that numbness might still be distressing to some patients. Additionally, neuroplastic processes termed central sensitisation may occur without nerve injury and may result in altered nociceptor function with a gain (sensitisation) or a loss (desensitisation) of function of nociceptors, resulting in sensory changes superficially resembling neuropathic pain. Assessment of these sensory changes using techniques such as quantitative sensory testing may in the future lead to more individualised treatment and drug development for the prevention and treatment of CPSP (Arendt-Nielsen 2018 **NR**).

The intensity and character of CPSP is variable. Descriptors may relate to neuropathic pain (shooting, burning, tingling) (VanDenKerkhof 2013 **Level IV**) but somatic / nociceptive pain characteristics (aching, tender, stabbing, squeezing) are also commonly reported (Chan 2011 **Level III-1**), especially associated with joint arthroplasty (Wylde 2011 **Level IV**, n=1,294). Typically around 10% of patients describe the CPSP as severe, although this proportion may be higher in some surgical groups (Glare 2019 **NR**). The sequelae of CPSP vary from mild discomfort to a significant impact on quality of life. The negative impact of CPSP is similar to that of other chronic pain conditions and, along with psychological distress, may include the use of multiple analgesics, regular medical attendances, inability to undertake certain activities and difficulty returning to work (Chan 2011 **Level III-1**, n=640; Steyaert 2012 **NR**).

1.4.3 | Opioids and CPSP

In recent years, the use of strong opioids to manage acute and chronic non-cancer pain has been increasing. This has been one factor in the generation of a global opioid crisis, with opioid use

and deaths from overdose of prescription drugs increasing dramatically in many countries (Jones 2018 **NR**). Surgery is a risk factor for both persistent pain and ongoing inappropriate opioid use (Hah 2017 **NR**). Prolonged opioid use after hospital discharge seems to be relatively common, occurring in 10.5% of patients for greater than 90 d after surgery in an Australian study (Stark 2017 **Level IV**, n=970), and in 3% of opioid naïve patients at 90 d in a large cohort study from Canada (Clarke 2014 **Level IV**, n=39,140). In contrast, opioid use by outpatient pain clinics has been decreasing in chronic non-cancer pain due to lack of evidence for their efficacy (Dowell 2016 **GL**; Chou 2009 **GL**). For more details see also Section 8.13.

Not only is CPSP a risk factor for ongoing opioid use, but opioid use may trigger or worsen symptoms of CPSP (see also Section 1.4.4 below). The use of high dose opioids in the acute setting has been shown to activate neuroplastic processes which may result in CPSP (see also Sections 1.1, 4.3.1 and 9.7). Opioid induced hyperalgesia (OIH) is a state of increased sensitivity to noxious stimuli occurring after exposure to high dose opioids (usually remifentanil). Patients exposed to high dose opioids in the perioperative period have higher postoperative pain scores and increased opioid use. OIH may result in spiralling opioid use (Fletcher 2014 **Level I**, 24 RCTs, n=1,494). Endogenous opioid analgesic systems are protective against the development of CPSP (Eippert 2009 **Level III-1 EH**; Yarnitsky 2008 **Level IV**, n=62). Prolonged opioid use leads to internalisation of mu opioid receptors at a cellular level. This may impair the functioning of the endogenous opioid analgesic system and increase sensitivity to pain leading to OIH and potentially CPSP (Glare 2019 **NR**).

1.4.4 | Predictive factors for chronic postsurgical pain

Risk evaluation for CPSP enables clinicians to address identified risk factors before surgery. This guides planning and discussion regarding expectations, the scope of planned surgery and possibility of changed approaches to the anaesthesia, pain management and even the procedure itself. Risk factors for CPSP have been identified in the preoperative, intraoperative and postoperative periods, and cover 6 broad domains: genetic, demographic, psychosocial, pain, clinical, and surgical factors (Schug 2017 **NR**).

Demographic factors such as younger age for adults and female gender influence the frequency of CPSP, as do psychological factors such as anxiety, depression, catastrophising, fear of surgery and hypervigilance (Theunissen 2012 **Level IV SR**, 29 studies, n=6,628; Hinrichs-Rocker 2009 **Level IV SR**, 50 studies, n≈25,000; Weinrib 2017 **NR**). Very young age may be a protective factor as hernia repair in children <3 mth of age did not lead to chronic pain in adulthood (Aasvang 2007 **Level IV**, n=651). In children aged 8–18 y, "*parent pain catastrophising"* was the main risk factor for the development of CPSP (Page 2013 **Level IV**, n-83). The significance of each risk factor varies with the operation but pre-existing psychological factors (high state anxiety and pain magnification as a component of catastrophising) increased the risk across two types of surgery (TKA and breast cancer surgery) (Masselin-Dubois 2013 **Level III-2**, n=189; Weinrib 2017 **NR**).

The intensity of acute postsurgical pain is a consistent predictor of CPSP (Chan 2011 **Level II**, n=640, JS 5; Althaus 2012 **Level IV**, n=150). This has been shown following a wide range of procedures including breast surgery (Bruce 2014 **Level IV**, n=362), thoracic surgery (Yarnitsky 2008 **Level IV**, n=62; Katz 1996 **Level IV**, n=30), gynaecological surgery (VanDenKerkhof 2012a **Level IV**, n=433), Caesarean section (Nikolajsen 2004 **Level IV**, n=220), lower limb amputation (Hanley 2007 **Level IV**, n=57), total hip arthroplasty (THA) (Nikolajsen 2006 **Level IV**, n=1,231) and inguinal herniotomy (Aasvang 2010a **Level IV**, n=464). After thoracic surgery, higher acute pain intensity postoperatively predicted the incidence of CPSP (OR 1.80; 95%CI 1.28 to 2.77), nearly doubling the chance of developing chronic pain for each point increase on a 10-point numerical rating scale (NRS) (Yarnitsky 2008 **Level IV**, n=62). Large scale observational studies have confirmed the

importance of acute pain in the development of CPSP with a 10% increase in the percentage of time in severe acute pain associated with a 30% increase in the incidence of CPSP at 12 mth (Fletcher 2015 **Level IV**, n=3,120). Sensitisation and "wind-up" of nociceptive pathways within the CNS is thought to play a significant role in the establishment and maintenance of chronic pain following an intense nociceptive stimulus. Nociceptive processes occurring in the periphery, including nerve injury, are also implicated in the transition from acute to chronic pain (Baron 2013 **NR**).

Preoperative chronic pain is a universal risk factor (Johansen 2014 **Level IV**, n=12,981; VanDenKerkhof 2012a **Level IV**, n=433; Wylde 2011 **Level IV**, n=1,294; Aasvang 2010a **Level IV**, n=464). This is likely due to the increase in sensitivity of the nociceptive system found in patients with chronic pain. This may partly explain the relatively high rates of CPSP following THA and TKA (25 and 44% respectively) (Wylde 2011 **Level IV**, n=1,294). Preoperative pain was the predictor that most commonly demonstrated a significant relationship with persistent pain following TKA across uni- and multivariate analyses. In a meta-analysis of univariate models, the largest effect sizes were found for preoperative pain at other sites, catastrophising and depression (Lewis 2015 **Level I**, 28 RCTs, n=29,993). For data from multivariate models catastrophising, preoperative pain, mental health and comorbidities had significant effects. Preoperative pain was also a risk factor for CPSP at 3 mth in trauma patients requiring orthopaedic surgery (OR: 1.17; 95% CI: 1.03, 1.32) (Edgley 2019 **Level III-2**, n=229).

Given the potential for opioids to interfere with endogenous analgesic systems, it is perhaps not surprising to find that preoperative opioid use increased the risk of CPSP after gynaecological surgery (RR 2.0; 95%CI 1.2 to 3.3) (VanDenKerkhof 2012a **Level IV**, n=433). In a prospective study of day case orthopaedic surgery, 8% developed CPSP if they were taking pre-operative analgesics with adequate analgesia (Hoofwijk 2015 **Level IV**, n=908). However, patients taking analgesics without relief had a much higher incidence of CPSP of 32%.

Presurgical sensitivity to painful stimuli, identified using some form of quantitative sensory testing (QST), variably accounts for 5–54% of the variance in acute postoperative pain and can predict risk for CPSP (Werner 2010 **Level I** [QUOROM], 15 RCTs, n=962). The relative efficacy of the endogenous descending inhibitory system determined by assessing DNIC partly predicted patients who developed CPSP after thoracotomy (OR 0.52; 95%CI 0.33 to 0.77) (Yarnitsky 2008 **Level IV**, n=62). Widespread pressure pain sensitivity was correlated with worse functional outcome following TKA (Wylde 2013 **Level III-3**, n=51). Sensitivity to noxious heat and mechanical stimuli did not correlate with CPSP in an unselected surgical population, whereas cold sensitivity correlated both with CPSP and comorbid chronic pain conditions (Johansen 2014 **Level IV**, n=12,981). Prior to herniotomy, high pain scores from a 47°C temperature probe were predictive of postherniotomy pain (OR 1.34; 95%CI 1.15 to 1.57) (Aasvang 2010a **Level IV**, n=464).

It is also likely that genetic and epigenetic factors influence both the sensitivity of individuals to analgesics and their risk of CPSP (Mauck 2014 **NR**; Buchheit 2012 **NR**). For example, different haplotypes of the gene for the enzyme catechol-O-methyltransferase (*COMT*), involved in the modulation of pain responses, were associated not only with differences in experimental pain sensitivity but also with the development of chronic temporomandibular joint disorder (TMD) (Nackley 2007 **Level IV**). In women undergoing hysterectomy the polymorphism rs4818 within the *COMT* gene was associated with the presence of CPSP at 3 mth but not 12 mth postoperatively (Hoofwijk 2019 **Level III-2**, n=345). However, opioid receptor mu-1 (*OPRM1*) genotype, but not *COMT* genotype, was associated with the development of CPSP after abdominal surgery (Kolesnikov 2013 **Level IV**, n=102). One prospective study of patients undergoing various surgical procedures did not reveal any correlation between 90 genetic markers and the incidence or severity of CPSP (Montes 2015 **Level IV**,

n=2,929). Overall, heritability estimates suggest that about 50% of the variability in CPSP rates is attributable to genetic variability. In order to apply these findings to individual patients, very large studies analysing tens of thousands of genetic samples will be needed to characterise patients at risk (Clarke 2015 **NR**) (see also Section 1.7).

To date, clinical risk factors remain the most reliable tools for the prediction of CPSP (Althaus 2012 **NR**). Attempts have been made to generate predictive models of CPSP but these do not yet have sufficient sensitivity and specificity to prove clinically useful. Using a training set of 150 patients with an incidence of CPSP of about 50%, five factors were independently predictive of developing CPSP, of which four can be assessed pre-operatively: pain in the surgical field, comorbid chronic pain at other sites, capacity overload and comorbid stress. Moderate to severe postoperative pain at POD 5 was the only significant postoperative factor. Patients with three to five risk factors were more likely to go on to develop CPSP than were those with zero to two factors (sensitivity 74%, specificity 65%).

Screening tools based on specific types of surgery have demonstrated better specificity, but identify many false positives. For example, for breast cancer surgery four factors were predictive of CPSP: preoperative pain at the site of surgery, high body mass index, axillary lymph node dissection and severity of acute pain on the 7th d after surgery (Meretoja 2017 **NR**). At the 20% risk level, the model had 32.8% and 47.4% sensitivity and 94.4% and 82.4% specificity in two cohorts from Denmark and Scotland, respectively. A predictive model for CPSP after inguinal hernia repair, hysterectomy or thoracotomy has been developed (Montes 2015 **Level IV**, n=2,929). The model included six clinical factors: surgical procedure, age, physical health, mental health, preoperative pain in the surgical field, and preoperative pain in another area. This model was a good fit (c-statistic 0.731; 95%CI 0.705 to 0.755). Interestingly, the same study found that 90 genetic markers did not predict CPSP.

The trajectory of daily pain scores after surgery has also been investigated as a predictor of CPSP (Chapman 2011 **Level IV**, n=502). Following TKA, 4 distinct acute pain trajectories were identified. Patients with a constantly high acute pain trajectory were at higher risk of CPSP (Page 2015 **Level IV**, n=173). Subacute pain after orthopaedic surgery at 10 d and 6 wk also predicted CPSP at 12 mth in one study (Andersson 2015 **Level IV**). Trajectories of anxiety and depression over time have also been assessed as a potential risk factor for CPSP, and patients with unremitting high levels of anxiety, but not depression were found to be more likely to experience CPSP following cardiac surgery (Page 2017 **Level IV**, n=173).

A summary of risk factors identified for the development of CPSP is presented in Table 1.3.

Table 1.3 | Risk factors for chronic postsurgical pain

Preoperative factors	Pain, moderate to severe, lasting >1 mth Repeat surgery Psychological vulnerability (eg catastrophising) Preoperative anxiety Female sex Younger age (adults) Workers' compensation Genetic predisposition Inefficient diffuse noxious inhibitory control Opioid use (particularly if ineffective)
Intraoperative factors	Surgical approach with risk of nerve damage
Postoperative factors	Pain (acute, moderate to severe and subacute) Radiation therapy to area Neurotoxic chemotherapy Depression Psychological vulnerability Neuroticism Anxiety Pain and anxiety trajectories

Sources: Adapted from Page 2017; Schug 2017; Johansen 2014; Wylde 2011; Hinrichs-Rocker 2009; Macrae 2008; Kehlet 2006.

1.4.5 | Mechanisms for the progression from acute to chronic pain

Central and peripheral sensitisation are the most likely underlying factors in the development of CPSP (Richebe 2018 **NR**; Lavand'homme 2017 **NR**). There is limited trial data to infer mechanisms and therefore most evidence relating to likely mechanisms is based on laboratory animal or epidemiological data (Peirs 2016 **NR BS**). Initiation of these processes is most likely in a situation where an individual is "primed" (eg by pre-existing pain) or susceptible (eg inefficient DNIC, psychological state or genetic predisposition) (Lavand'homme 2017 **NR**; Denk 2014 **NR**; Lavand'homme 2011 **NR**). The imposition of an intense surgical stimulus induces both central and peripheral changes (Baron 2013 **NR**). Maintenance of these intense nociceptive inputs by poorly controlled postoperative pain, peripheral nerve damage (D'Mello 2008 **NR**) and complications (eg wound infection) then lead on to a chronic pain state. It is proposed that these all lead to neuroplastic processes such as peripheral and central sensitisation. Such processes include inflammation at the site of tissue damage as well as ectopic discharges after nerve injury and lead to a barrage of afferent input that produces changes in the peripheral nerves, spinal cord, higher central pain pathways, somatosensory cortex and the sympathetic nervous system (see Section 1.1). Evidence for sensitisation includes the presence of larger area of secondary hyperalgesia at 48 h (88 vs 33 cm^2) in patients having iliac crest bone harvesting who developed CPSP with higher neuropathic pain scores on the Doleur Neuropathique 4 (DN4) questionnaire (4.3/10 vs 2.3) (Martinez 2012 **Level IV**). Similarly, following abdominal surgery, patients with analgesic regimens resulting in smaller areas of wound hyperalgesia (indicating less sensitisation) had a lower incidence of CPSP (Lavand'homme 2005 **Level II**, n=85, JS 5). Punctuate hyperalgesia

around a surgical incision could be shown in a large area, suggesting central sensitisation, which was suppressed by IV ketamine injection (Stubhaug 1997 **Level II**, n=20, JS 5).

The relative degree of ongoing inflammation or intraoperative nerve injury resulting in peripheral and central sensitisation may explain the variation in risk and, to an extent, the characteristics of CPSP for different operations (Simanski 2014 **Level IV**).

Psychological factors (depression, psychological vulnerability and stress) are important in the development of CPSP (Hinrichs-Rocker 2009 **Level IV SR**, 50 RCTs, n≈25,000) and cortical processing of nociceptive information and descending inhibitory and excitatory pathways provides a plausible mechanism for some of these effects. Functional connectivity and anatomical differences of corticolimbic structures involved in emotion and motivation predict chronic pain in some circumstances (Vachon-Presseau 2016 **Level IV EH**; Baliki 2012 **NR**).

1.4.6 | Prevention of chronic postsurgical pain

Effective prevention of CPSP is limited by an incomplete understanding of the mechanisms that generate it. However, some recognised risk factors are modifiable in the perioperative period. These include, body mass index, opioid use, preoperative pain and some psychological factors. In the postoperative period, attention to effective management of acute pain, limiting exposure to opioids and psychological support in rehabilitation and recovery of normal functioning are all likely to play a role.

Interventions evaluated thus far are divided into four broad groups and include regional and neuraxial analgesia, pharmacotherapy, surgery and multidisciplinary nonpharmacological interventions. Analgesic strategies for which the clinical efficacy outlasts the pharmacological activity are described as “preventive analgesia” (defined as analgesia that persists more than 5.5 half-lives of the medicine) and most likely rely on reducing peripheral and central sensitisation (Katz 2011 **NR**) (see also Section 1.5).

1.4.6.1 | Regional or neuraxial analgesia

Meta-analysis on the prevention of CPSP by regional anaesthesia found benefits for three procedure types: thoracotomy, breast cancer surgery and Caesarean section (Weinstein 2018 **Level I** (Cochrane), 63 RCTs, n=3,027). Following open thoracotomy (7 RCTs, n=499), epidural anaesthesia reduces the incidence of CPSP 3 to 18 mth following surgery compared to systemic analgesia (OR 0.52; 95%CI 0.32 to 0.84) (number-needed-to-treat [NNT] 7). For breast cancer surgery any form of regional anaesthesia (18 RCTs, n=1,297) reduces CPSP 3 to 12 mth after surgery compared with systemic analgesia (OR 0.43; 95%CI 0.28 to 0.68) (NNT 7); specifically paravertebral block (PVB) (6 RCTs, n=419) is effective (OR 0.61; 95%CI 0.39 to 0.97) (NNT 11). For Caesarean section (4 RCTs, n=551), a mixture of regional analgesia techniques, reduces CPSP from 3 to 8 mth (OR 0.46; 95%CI 0.28 to 0.78) (NNT 19). There is insufficient data to make clear recommendations regarding the timing of various local anaesthetic interventions (21 RCTs) and the impact on CPSP, but earlier administration of epidural prior to incision vs post amputation (4 RCTs, n=334) may provide benefit (Humble 2015 **Level I**, 32 RCTs, n=2,834).

For many procedures, studies investigating the effect of regional anaesthesia and analgesia on chronic pain outcomes are limited in number and have differing designs, which prevents meta-analysis due to high levels of heterogeneity. In patients undergoing open colonic resection, continuous perioperative epidural analgesia led to a lower risk of developing chronic pain up to 1 y after surgery compared with IV analgesia (Lavand'homme 2005 **Level II**, n=85, JS 5). In a case-control study, epidural anaesthesia reduced chronic pain at 6 mth after surgery (OR 0.19; 95%CI 0.05 to 0.76) (Bouman 2014 **Level III-2**). Spinal anaesthesia in comparison to general anaesthesia

reduced the risk of CPSP after Caesarean section (Nikolajsen 2004 **Level III-2**) and hysterectomy (OR 0.42; 95%CI 0.21 to 0.85) (Brandsborg 2007 **Level III-2**). The latter study found no difference in risk between abdominal and vaginal hysterectomy.

A systematic review on phantom limb pain prophylaxis showed that perioperative (pre, intra and postoperative) epidural analgesia reduced the incidence of severe phantom limb pain 12 mth after surgery (NNT 5.8) (Gehling 2003 **Level III-2 SR**, 9 studies, n=836). The use of epidural analgesia to prevent the development of phantom pain or CPSP following limb amputation may be a useful component of multimodal therapy in patients with severe preoperative pain (Karanikolas 2011 **Level II**, n=65, JS 5). See also Section 8.1.5.

The use of IV lidocaine for prevention of CPSP is discussed in Section 1.4.6.3 below.

1.4.6.2 | Local anaesthetic infiltration

Meta-analysis on the prevention of CPSP by local infiltration finds benefits for breast cancer surgery and iliac crest bone graft (ICBG) harvest (Weinstein 2018 **Level I** [Cochrane], 39 RCTs, n=3,027). For breast cancer surgery (6 RCTs, n=379), local anaesthetic infiltration reduces CPSP 3 to 12 mth after surgery vs systemic analgesia (OR 0.29; 95%CI 0.12 to 0.73) (NNT 7). For ICBG harvest (4 RCTs, n=159), continuous local anaesthetic infiltration reduces CPSP 3 to 12 mth after surgery vs systemic analgesia (OR 0.1; 95%CI 0.01 to 0.59) (NNT 3).

Local anaesthetic wound infiltration reduced the proportion of patients with chronic pain and neuropathic pain 2 mth following intracranial tumour resection (Batoz 2009 **Level II**, n=52, JS 3).

1.4.6.3 | Pharmacotherapy

Ketamine

Ketamine is commonly used to treat both acute and chronic pain. When used as a preventive analgesic, perioperative ketamine compared to placebo significantly reduces CPSP at 3 mth (5 RCTs, n unspecified) but only when administered for >24 h (OR 0.37; 95%CI 0.14 to 0.98) (Chaparro 2013 **Level I** [Cochrane], 14 RCTs [ketamine], n=1,388). At 6 mth (10 RCTs, n=516), perioperative ketamine reduces CPSP (OR 0.63; 95%CI 0.47 to 0.83), which remains significant when infused for <24 h (OR 0.45; 95%CI 0.26 to 0.78). These effects were predominantly in abdominal surgery. Another meta-analysis found a benefit of perioperative IV ketamine vs placebo in reducing the incidence of CPSP at 3 mth (RR 0.74; 95%CI 0.60 to 0.93) (NNT 12), 6 mth (RR 0.70; 95%CI 0.50 to 0.98) (NNT 14) but not at 12 mth postoperatively (McNicol 2014 **Level I**, 14 RCTs [IV route], n=1,586) (11 RCTs overlap); such beneficial effects were not found with epidural administration of ketamine (3 RCTs, n=302).

A network meta-analysis investigating multiple pharmacological interventions to reduce CPSP identified ketamine as the highest ranked in terms of efficacy and safety (Ning 2018 **Level I** [NMA], 24 RCTs, n unspecified). In thoracic surgery, low dose ketamine infusion (0.1 mg/kg/hr) reduced opioid use for 24 h and pain at 48 h, but did not affect CPSP at 3, 6 or 12 mth (Chumbley 2019 **Level II**, n=70, JS 5).

Opioids

High dose intra-operative opioids, particularly remifentanil, have been shown to result in opioid induced hyperalgesia, increased pain and 24 h opioid use in the postoperative period which may be associated with CPSP (Fletcher 2014 **Level I**, 27 RCTs, n=1,494). The intra-operative use of remifentanil in cardiac surgery also resulted in a higher incidence of CPSP at 1 y (OR 8.9; 95%CI 1.6 to 49.0) (van Gulik 2012 **Level III-2**, n=90).

Alpha-2-delta ligands (gabapentinoids)

Two previous parallel meta-analyses (10 RCT overlap) and a correction of one of these investigated the use of perioperative gabapentin or pregabalin in reducing CPSP across a diverse range of procedures (Chaparro 2013 **Level I** [Cochrane], 15 RCTs [gabapentin and pregabalin], n=1,300; Clarke 2012 **Level I** [PRISMA], 11 RCTs, n=930; Clarke 2013 **Level I**, 5 RCTs, n=875). The overall conclusion was that there was limited or no benefit in the setting of significant heterogeneity.

In addressing the issue of potential bias due to unpublished data, a meta-analysis of pregabalin and CPSP included 79% unpublished trials (Martinez 2017 **Level I** [PRISMA], 18 RCTs, n=2,485). There was no benefit with pregabalin use in the prevention of CPSP overall at 3, 6 or 12 mth postoperatively, in cardiac, visceral or orthopaedic surgery (OR 0.87 [at 3 mth]; 95%CI 0.66 to 1.14). There was, however, a reduction in chronic postsurgical neuropathic pain in four published trials (4 RCT, n=451) (OR 0.16; 95%CI 0.04 to 0.73). These results reflect weak evidence due to the small size of most included studies, the variability in existing study design, doses used, duration of treatment and measured outcomes, and positive publication bias.

IV lidocaine (lignocaine)

IV lidocaine has preventive effects on acute postoperative pain (Barreveld 2013 **Level I**, 16 RCTs [lidocaine], n=847) (see Section 1.5) and reduces CPSP following breast cancer surgery at 3 mth compared to systemic analgesics alone (OR 0.24; 95%CI 0.08 to 0.69) (Weinstein 2018 **Level I** [Cochrane], 2 RCTs, n=97 [IV lidocaine]) (1 RCT overlap). A meta-analysis of IV lidocaine versus placebo in the prevention of CPSP at 3 mth across a range of surgeries (predominantly mastectomy), identified a significant benefit (OR 0.29; 95%CI 0.18 to 0.48) (NNT 5), although numbers were too small to specifically identify safety concerns (Bailey 2018 **Level I**, 6 RCTs, n=420) (2 RCT overlap with Weinstein 2018).

Others

Following mastectomy, 10 d treatment with venlafaxine (37.5 mg/d) commencing preoperatively was associated with significantly lower burning and stabbing pain after 6 mth (Amr 2010 **Level II**, n=150, JS 3).

Planned subgroup analysis of the intraoperative use of nitrous oxide (ENIGMA-2) revealed that this intervention prevents CPSP in Chinese patients and those with variants in the methylene tetrahydrofolate reductase gene (RR 0.70; 95%CI 0.50 to 0.98) suggesting that there may be a genetic component to vulnerability to CPSP (Chan 2016 **Level II**, n=674, JS 5); there was no benefit in non-Chinese patients overall.

1.4.6.3 | Modification of surgical approach

Minimally invasive and laparoscopic surgery has made a significant impact on the severity of acute postsurgical pain but has resulted in little impact on the prevalence of CPSP (Aasvang 2010a **Level III-2**, n=464). While VATS vs open thoracic surgery reduced the risk of post-thoracotomy pain (aOR 0.33; 95%CI 0.13 to 0.86) and neuropathic pain (aOR 0.18; 95%CI 0.04-0.85), it still carries a significant risk (35% incidence) (Shanthanna 2016 **Level III-3**, n=106); this is confirmed in another study (VATS 13.3% vs thoracotomy 32.2%) (Wang 2017 **Level III-2**, n=298).

Deliberate neurectomy (of the ilioinguinal nerve) for inguinal hernia repair reduced the incidence of CPSP (from 21 to 6%) in one RCT (Malekpour 2008 **Level II**, n=100, JS 4) and in another study (Smeds 2010 **Level III-2**), while an earlier nonrandomised multicentre prospective study found this approach increased CPSP risk (Alfieri 2006 **Level III-2**, n=973). Intraoperative nerve identification of the iliohypogastric, ilioinguinal and genitofemoral nerves did not reduce the risk of development of sensory loss or postherniotomy pain syndrome compared with nonidentification (Bischoff 2012 **Level III-3**, n=244). International

guidelines for the reduction in CPSP following inguinal herniorrhaphy have been developed, recommending preservation of all three nerves (Alfieri 2011 **GL**).

Sparing of the intercostobrachial nerve during mastectomy with axillary dissection reduces the likelihood of a patient having hyposensitivity but not hypersensitivity (Warrier 2014 **Level I** [PRISMA], 3 RCTs, n=309). Cryoanalgesia of the intercostal (IC) nerves at the time of thoracotomy results in an increase in chronic pain in comparison to IV PCA or epidural analgesia or in conjunction with epidural analgesia (Humble 2015 **Level I**, 6 RCTs [cryoanalgesia], n=186).

1.4.6.4 | Multidisciplinary approaches

The impact of psychological interventions delivered in the perioperative period to prevent CPSP has been assessed by a systematic review (Wang 2018 **Level I** [PRISMA], 15 RCTs, n=2,220). Perioperative education has no effect on CPSP, while perioperative cognitive-behavioural therapy and/or relaxation training reduce the severity of CPSP based on evidence of moderate quality (MD -1.06/10; 95%CI -1.56 to -0.55). Preemptive and preventive pain psychoeducation decrease the length of stay and improve quality of acute postsurgical pain relief (Horn 2020 **Level I** [PRISMA], 43 RCTs, n unspecified). The authors concluded that preemptive pain psychoeducation would result in a decreased incidence of CPSP given that severe acute postsurgical pain and catastrophising were both significant risk factors.

Transitional pain services

New models of acute pain services have been suggested to manage pain and opioid use in the perioperative period. The '*Transitional Pain Service*' aims to optimise pain and opioid use prior to surgery, devise individualised intraoperative opioid sparing analgesic plans and manage pain postoperatively beyond the time of discharge from hospital (Katz 2015 **NR**). This approach is intended to reduce CPSP and inappropriate long-term opioid use. Psychological strategies including Acceptance and Commitment Therapy (ACT) are employed to assist in rehabilitating patients and treat or prevent CPSP (Huang 2016 **NR**). A similar model of '*Acute Pain Service Outpatient Clinic*' has been established in Finland (Tiippana 2016 **Level III-3**). Of the first 200 high risk patients referred to the clinic, 70% had evidence of neuropathic CPSP. The median time to referral to the clinic from surgery was 2 mth and patients were followed up for a median of 2.8 mth. At discharge from hospital, half the patients were using weak opioids, one third strong opioids and 70% were taking gabapentinoids. At discharge from the clinic, use of these drugs was approximately halved. One fifth of the patients were referred to the chronic pain clinic for ongoing management.

See also the following Section 1.5 for more examples of the use of preemptive and preventive analgesic interventions in attempts to reduce the risk of chronic pain after surgery and Sections 8.1.5 to 8.1.6 for more details on prevention of phantom pain after limb amputation and other postoperative pain syndromes.

KEY MESSAGES

1. Perioperative IV ketamine reduces the incidence of chronic postsurgical pain in selected procedures (**S**) (**Level I** [Cochrane Review]).
2. Following thoracotomy, epidural analgesia reduces the incidence of chronic postsurgical pain (**S**) (**Level I** [Cochrane Review]).
3. Following breast cancer surgery, paravertebral block (**S**), local infiltration (**N**) (**Level I** [Cochrane Review]) and IV lidocaine reduce the incidence of chronic postsurgical pain (**N**) (**Level I** [PRISMA]).
4. For iliac crest bone graft harvest, continuous local anaesthetic infiltration reduces the incidence of chronic postsurgical pain (**N**) (**Level I** [Cochrane Review])
5. Pregabalin reduces the incidence of chronic postsurgical neuropathic pain, but does not affect non-neuropathic chronic postsurgical pain (**N**) (**Level I** [PRISMA]).
6. Sparing of the intercostobrachial nerve during mastectomy does not decrease chest wall hypersensitivity (**U**) (**Level I** [PRISMA]).
7. Cryoanalgesia of the intercostal nerves at the time of thoracotomy results in no improvement in acute pain but an increase in chronic pain (**U**) (**Level I**).
8. There is significant association between anxiety, pain catastrophising (**U**) (**Level III-2 SR**), depression, psychological vulnerability and stress (**U**) (**Level IV SR**) and the subsequent development of chronic postsurgical pain.
9. Other risk factors that predispose to the development of chronic postsurgical pain include the severity of presurgical chronic pain and postsurgical acute pain and intraoperative nerve injury (**U**) (**Level IV SR**).
10. Spinal anaesthesia in comparison to general anaesthesia reduces the risk of chronic postsurgical pain after hysterectomy and Caesarean section (**U**) (**Level III-2**).
11. Chronic postsurgical pain is common and may lead to significant disability (**S**) (**Level IV**).
12. Chronic postsurgical pain often has a neuropathic component (**S**) (**Level IV**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Gabapentin has no demonstrated effect in preventing chronic postsurgical pain; considerable uncertainty exists regarding efficacy with contradictory meta-analyses of a few, usually small, studies with a large degree of heterogeneity (**Q**).

☑ Implementation of transitional pain services may help manage the complex issues of prolonged postoperative opioid use and chronic postsurgical pain (**N**).

1.5 | Pre-emptive and preventive analgesia

The terms 'pre-emptive' and 'preventive' analgesia have a highly specific meaning with respect to pain neurophysiology and sensitisation. The understanding of pre-emptive analgesia has evolved since the term was first coined in early 1988 (Wall 1988 **NR**). In laboratory studies, administration of an analgesic prior to an acute nociceptive stimulus more effectively minimised dorsal horn changes associated with central sensitisation than the same analgesic given after the pain state was established (see Section 1.1) (Woolf 1983 **BS**). This led to the hypothesis that pain relief prior to surgery may enhance postoperative pain management when compared with the same analgesia administered during or following surgery; that is, "pre-emptive preoperative analgesia" (Wall 1988 **NR**). However, individual clinical studies have reported conflicting outcomes when comparing "preincisional" with "postincisional" interventions. In part this relates to variability in definitions, deficiencies in clinical trial design and differences in the outcomes available to laboratory and clinical investigators (Rosero 2014a **NR**; Katz 2002 **NR;** Kissin 1994 **NR**).

Central and peripheral sensitisation affects both the intensity of acute pain and the persistence of pain well into the postoperative period and beyond (see also Section 1.4). This is complex and relates not only to the skin incision but also to the extent of intraoperative tissue and nerve injury, postoperative inflammation and the nervous system's response. The research focus has shifted from the "timing" of a single analgesic intervention to the concept of modifying sensitisation and thus having a longer-term impact on pain relief. This is termed "preventive" analgesia (Kissin 1994 **NR**) rather than pre-emptive analgesia. The differences between these two terms relate to the timing and outcomes being described, because both aim to minimise sensitisation. "Pre-emptive" analgesia, as described above, relates to the timing of administration of the analgesic intervention prior to the insult and is measured in terms of pain intensity or related outcomes. "Preventive" analgesia is the persistence of analgesic treatment efficacy beyond its expected duration of effect (see Table 1.4). This had been defined as analgesia that persists for >5.5 half-lives of a medicine, to ensure complete washout of any direct pharmacological effect (Katz 2011 **NR**). A useful summary of medicines and their criterion value of 5.5 half-lives has been published (Katz 2008b **NR**). In clinical practice, preventive analgesia appears to be the most relevant and, of pharmacological options, holds the most hope for minimising chronic pain after surgery or trauma because it decreases central sensitisation and "wind-up". An important consideration to maximise the benefit of any analgesic strategy is that the active intervention should be continued for as long as the sensitising stimulus persists (ie well into the postoperative period) (Pogatzki-Zahn 2006 **NR**; Dahl 2004 **NR**). However, from a "preventive" perspective, the critical aspect is that the effect of the intervention is sufficient to modify sensitisation and hence longer-term outcomes; the timing and duration for specific interventions still require clarification.

Table 1.4 | Definitions of pre-emptive and preventive analgesia

Pre-emptive analgesia	Preoperative treatment is more effective than the identical treatment administered after incision or during surgery. The key clarification point is the timing of administration "pre" insult/surgery. A treatment given pre-emptively can also be preventive if it satisfies the below definition.

Preventive analgesia	Postoperative pain and/or analgesic consumption is reduced relative to another treatment, a placebo treatment or no treatment with the effect observed at a point in time beyond the expected duration of action of the intervention (eg 5.5 half-lives of the medicine). The intervention may or may not be initiated before surgery.

Sources: Moiniche 2002; Katz 2002; Katz 2011; Rosero 2014b

1.5.1 | Pre-emptive analgesia

The benefits of pre-emptive analgesia have been questioned (Katz 2008b **Level I**, 27 RCTs, n unspecified; Moiniche 2002 **Level I**, 80 RCTs, n=3,761; Dahl 2004 **NR**). However, one meta-analysis provided support for pre-emptive analgesia (Ong 2005 **Level I**, 66 RCTs, n=3,261). The efficacy of different pre-emptive analgesic interventions (epidural analgesia, local anaesthetic wound infiltration, systemic NMDA antagonists, systemic opioids and systemic NSAIDs) was analysed in relation to different analgesic outcomes (pain intensity scores, supplemental analgesic consumption, time to first analgesic). The effect size is most marked for epidural analgesia, with improvements found in all outcomes (13 RCTs, n=653) (overall effect size 0.38; 95%CI 0.28 to 0.47). Pre-emptive effects of local anaesthetic wound infiltration and NSAID administration were also suggested but reanalysis is required as one of the positive studies for each of these treatments has subsequently been withdrawn (White 2011 **NR**). As a result of this withdrawal, evidence supporting the pre-emptive effects of nonselective NSAIDS (nsNSAIDs) and COX-2 inhibitors is equivocal (White 2009 **NR**). Reductions in analgesic consumption ranged from 44–58%, which the authors regarded as clinically significant, but associated changes in adverse effects were not analysed. Pain score results were equivocal for systemic NMDA antagonists (effect size [ES] 0.00; 95%CI -0.19 to 0.20) (7 RCTs, n=418) and there was no clear evidence for a pre-emptive effect of opioids (ES -0.24; 95%CI -0.46 to -0.01) (7 RCTs, n=324).

Following thoracotomy, pre-emptive thoracic epidural analgesia (local anaesthetic ± opioid prior to surgery) reduces the severity of acute pain on coughing for up to 48 h, with a marginal effect on pain at rest compared with the same therapy initiated postoperatively (Bong 2005 **Level I**, 6 RCTs, n=458). Acute pain intensity was a predictor of chronic pain at 6 mth in two studies but there was no statistically significant difference in the incidence of chronic pain between the pre-emptive epidural (39.6%) vs control epidural (48.6%) groups. Pre-emptive analgesia with epidural use in thoracotomy identified lower postoperative pain scores, reduced pro-inflammatory biomarkers and shortened hospital LOS (Yang 2015 **Level II**, n=90, JS 3).

In single-stage TKA, pre-emptive epidural analgesia was associated with lower postoperative pain scores, fewer days with pain following surgery (mean ± SD 64.3 d ± 21.3 vs 142.4 d ± 80.0) and less CPSP at 3 mth (24 vs 56.5%) (Rao 2020 **Level II**, n=50, JS 3); there were no differences in morphine consumption or LOS.

A Cochrane review investigated opioids commenced prior to incision compared to those commenced following incision; this review uses the term “preventive” to indicate the continued use of opioids into the postoperative period and so its findings are actually more in line with the above definition of “pre-emptive” (Doleman 2018 **Level I** [Cochrane], 20 RCTs, n=1,343). There were no differences in 6 h or 24 to 48 h pain score outcomes, but a small reduction was found in 24 h morphine consumption in the pre-incision group (MD -4.9 mg; 95%CI -9.4 to -0.4).

Across a range of procedures, IV paracetamol given before incision is more effective than post incision in reducing pain at 1 h (MD -0.50/10; 95%CI -0.98 to -0.02) and 2 h (MD -0.34/10; 95%CI - 0.67 to -0.01), 24 h opioid consumption (SMD 0.52; 95%CI -0.98 to -0.06) and

postoperative vomiting (RR 0.50; 95%CI 0.31 to 0.83) (Doleman 2015 **Level I** [PRISMA], 7 RCTs, n=544). IV paracetamol reduces PONV when administered before recovery from anaesthesia (Apfel 2013 **Level I** [PRISMA], 30 RCTs, n=2,364). This effect is correlated to pain relief achieved but not to reduced opioid consumption.

In total abdominal hysterectomy, gabapentin given only prior to surgery compared to gabapentin given pre- and postoperatively found both interventions decreased 24 h morphine requirements compared to placebo (preoperatively only SMD -0.69; 95%CI -1.20 to-0.07; pre and postoperatively -1.45; 95% CI -1.79 to -1.11) (Alayed 2014 **Level I SR**, 14 RCTs, n=891); the effect of gabapentin in reducing morphine consumption was stronger in the preoperative only group than in the preoperative and postoperative group. The design of the studies in this meta-analysis did not allow for evaluation of a true pre-emptive effect because all active treatments were given preoperatively.

Dexketoprofen administered 30 min pre- vs 10 min post-incision in patients having abdominal hysterectomy resulted in lower pain scores for up to 4 h postoperatively and reduced morphine consumption for up to 24 h (Gelir 2016 **Level II**, n=50, JS 3); all patients received intraoperative ketamine infusions and there was no difference in time to first analgesic request.

A combination of paracetamol, ketoprofen and pregabalin administered 4 h pre-surgery vs control, with all drugs being then given to both groups post-incision for at least 48 h, resulted in improved pain scores for up to 48 h and reduced PCA opioid requirements (Raja 2019 **Level II**, n=97, JS 4).

The reason for there being a limited number of valid clinical studies investigating 'pre-emptive' analgesia is that investigators often fail to compare the same technique pre- and post-incision or they apply the intervention after sensitisation has occurred eg in trauma or injury. The variability in clinical trial design coupled with the complexity of clinical pain management means that, with the exception of epidural analgesia, benefits remain unclear regarding pre-emptive analgesia in a clinical setting.

1.5.2 | Preventive analgesia

A true preventive analgesic effect needs to be assessed many days or even months after the analgesic intervention has ceased. A large number of studies published use the term 'preventive' where the investigation often simply compares the addition of a preoperative dose of an analgesic to a preoperative placebo (possibly continuing the medications postoperatively) with analgesic outcomes assessed for a relatively short period – this is not 'preventive' in the neurophysiological sense and such studies are not discussed here.

A systematic review analysed dichotomous trial outcomes (overall positive or negative outcomes) (Katz 2008b **Level I**, 39 RCTs, n unspecified) and identified overall beneficial acute preventive effects following the use of a range of different medicines (28 positive RCTs, 11 negative RCTs). Again, results of this meta-analysis might be affected by the subsequent withdrawal of some of the studies included (White 2011 **NR**). The methodology was unable to identify specific therapeutic techniques that may be of benefit.

The use of local anaesthetics (neuraxial, perineural or systemic) demonstrates a preventive analgesic effect in the perioperative period whether given pre- or postincision (Weinstein 2018 **Level I** (Cochrane), 63 RCTs, n=3,027; Barreveld 2013 **Level I**, 89 RCTs, n unspecified). Meta-analysis on the prevention of CPSP by regional anaesthesia found benefits for three procedure types: thoracotomy, breast cancer surgery and Caesarean section (Weinstein 2018 **Level I** (Cochrane), 63 RCTs, n=3,027). IV lidocaine versus placebo provides a significant benefit in prevention of CPSP at 3 mth across a range of surgeries (Bailey 2018 **Level I**, 6 RCTs, n=420) (2 RCTs overlap with Weinstein 2018 **Level I** [Cochrane]) 2 RCTs, n=97 [IV lidocaine]) (see Section 1.4 for details).

Activation of the NMDA receptor plays an important role in central sensitisation and many studies have focussed on the ability of NMDA-receptor antagonists to produce pre-emptive or preventive analgesic effects. A medicine which, when used perioperatively, reduces CPSP has by definition a preventive analgesic effect (see Section 1.4). The preventive effects of perioperative ketamine, dextromethorphan and magnesium on CPSP are described in Sections 1.4 and 4.6. Analgesic benefit is seen in the acute postoperative period with ketamine following a range of doses, timings and procedures (Laskowski 2011 **Level I** [PRISMA], 70 RCTS, n=4,701) supported by a network meta-analysis investigating multiple pharmacological interventions to reduce CPSP which identified ketamine as the highest ranked in terms of efficacy and safety (Ning 2018 **Level I** [NMA], 24 RCTs, n unspecified) (see also Section 4.6.1). However, in the immediate postoperative period, it is difficult to separate persistence of direct pharmacological effects from preventive actions, as many studies continued treatment for over 24 h. Expanding potential indications for ketamine in depression have led to exploration of its potential 'metaplastic' effects on synaptic transmission whereby a brief exposure may result in persisting changes in neuronal long term potentiation (Izumi 2014 **BS**); this may explain in part its effect in CPSP.

The alpha-2-delta ligands, gabapentin and pregabalin, reduce opioid requirements and improve analgesia when given perioperatively (see Section 4.8). However, even though some of these studies used only single-dose therapy, the range of doses, duration of follow-up and long half-life of gabapentin (6 to 7 h) means that an early preventive benefit is difficult to discern from a direct pharmacological effect. Longer term preventive effects on CPSP are discussed in Sections 1.4 and 4.8.

In a study of multimodal epidural analgesia (local anaesthetic, opioid, ketamine and clonidine) in four groups of patients having colonic resection, a clear preventive effect on the development of residual pain up to 1 y after surgery was demonstrated with continuous perioperative epidural analgesia (Lavand'homme 2005 **Level II**, n=85, JS 5). Residual pain at 1 y was lowest in patients who received intraoperative vs postoperative epidural analgesia. Epidural analgesia commenced pre-incision versus post-incision for TKA resulted in less CPSP at 3 mth (24 vs 56.5%) (Rao 2020 **Level II**, n=50, JS 3) indicating a possible preventive effect (see Section 1.5.1 above for other details).

Epidural calcitonin, bupivacaine and fentanyl versus epidural bupivacaine and fentanyl alone reduced phantom pain, allodynia and hyperalgesia at 6 and 12 mth following proximal or distal amputation in the lower limb (Yousef 2017 **Level II**, n=60, JS 3).

KEY MESSAGES

Pre-emptive analgesia

1. The timing of opioid administration (preincision rather than postincision) may reduce further opioid consumption over 24 h, but has no effect on pain scores **(N)** (**Level I** [Cochrane Review])
2. Pre-emptive use of paracetamol across a range of procedures reduces pain scores up to 2 h, opioid consumption for up to 24 h and postoperative nausea and vomiting (**N**) (**Level I** [PRISMA]).
3. Pre-emptive epidural analgesia has a significant effect on postoperative pain relief (**S**) (**Level I**).

Preventive analgesia

4. Epidural, regional and systemic local anaesthetic administration shows preventive analgesic effects in reducing chronic postsurgical pain (**S**) (**Level I** [Cochrane Review])
5. NMDA-receptor antagonists (ketamine) reduce the incidence of chronic postsurgical pain in selected procedures (**S**) (**Level I** [Cochrane Review]).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ In clinical trials assessing acute postoperative pain for many systemic medicines, the range of doses administered, the variable durations of follow-up and variable half-lives following infusion or repeated dosing means that "early" preventive effects, although possible, are difficult to discern from persistence of direct pharmacological effects (**U**).

1.6 | Adverse physiological and psychological effects of acute pain

1.6.1 | Acute pain and the injury response

Acute pain, and its associated injury and treatment, triggers a complex haemodynamic, metabolic, neurohumoral, immune as well as somatosensory response (see Figure 1.2) (Manou-Stathopoulou 2019 **NR**). Clinically, acute pain is commonly associated with actual tissue damage. This tissue damage may be due to trauma or surgery. The complete physiological response to the insult has a quantifiable molecular and cellular response. Importantly, this response is generated in a range of anatomical compartments. These include rapid adaptations at the site of injury, along ascending neuronal projections, within the spinal cord, at higher brain centres and within distal organs. These disparate events are triggered by a coordinated array of neuronal, autocrine and paracrine signalling events. Many of these events do not result in nociceptive outcomes but may detrimentally impact an individual's injury recovery or increase risk of secondary complications. Importantly, all of these events can occur in a conscious individual whose prior life experience may prime or protect them from the molecular consequences and perception-processing of a painful response.

Figure 1.2 | The injury response

Triggers and predisposing factors	Mediators	Injury response
Surgical trauma or injury	Neural	Pain experience, primary and secondary hyperalgesia (peripheral and central sensitisation)
Preoperative pain	Immune factors Proteins and other molecules: growth factors eicosanoids nitric oxide others	Inflammation Haemodynamic
Psychological factors	Endocrine	Catabolism
Social and environmental factors	Metabolic	Physical deconditioning
Genetic factors		Psychological effects
Anaesthesia and analgesia, other medications		Other adaptations systemic

Source: Modified from NHMRC 1999.

It is difficult to separate the complex array of potential individual or interacting triggers associated with pain from other aspects of the broader physiological response observed clinically (see Figure 1.2). However, some data have been obtained with experimental pain in the absence of injury. For example, electrical stimulation of the abdominal wall results in a painful experience

(intensity 8/10) and an associated hormonal/metabolic response, which includes increased levels of cortisol, catecholamines and glucagon, and a decrease in insulin sensitivity (Greisen 2001 **Level II EH**). A systematic review of the effect of experimental pain on the autonomic nervous system, assessed by heart rate variability, determined that experimental pain increases baroreflex activity and decreases parasympathetic activity (Koenig 2014 **Level IV EH SR**, 20 studies, n unspecified). Factors such as time of day, possibly owing to nociceptive control by diurnally active hormones, contribute to reported differences in thermal pain (both cold and heat) (Aviram 2015 **Level II EH**, n=48, JS 3). Some of these environmental conditioning factors may change the perception rather than the nociceptive signal itself eg sleep deprivation in healthy controls causes hyperalgesia which may be caused by a reduction in cortical cognitive or perceptual mechanisms, rather than sensory nociceptive amplification (Odegard 2015 **Level II EH**, n=33, JS 4).

Although acute pain is only one of the important triggers of the "injury response" (see Figure 1.2), as the magnitude and duration of the response is related to the magnitude and duration of the nociceptive stimulus, effective pharmacological pain relief may have a significant impact on this response (Moselli 2011 **Level II**, n=35, JS 3), although this may be variable (Fant 2013 **Level II**, n=26, JS 3; Liu 2008 **NR**; Carli 2008 **NR**). Beyond pharmacological interventions, mere distraction of attention away from the pain protects against experimental pain-induced changes in heart rate variability (Koenig 2014 **Level IV EH SR**, 20 studies, n unspecified). Importantly, negative expectations in patients created by verbal suggestions can lead to the "nocebo" response, defined as experiencing greater pain to the same nociceptive stimulus (Petersen 2014 **Level III-1 EH SR** [PRISMA], 10 studies, n=344).

As noted above, the release of systemic factors such as proinflammatory cytokines as a result of pain and trauma associated with surgery or injury may contribute to multiple physiological responses that hamper the recovery of a patient (Manou-Stathopoulou 2019 **NR**). Limiting these effects by analgesic techniques may affect some surgical outcomes. A group of patients having abdominal surgery were randomised to receive intraoperative epidural analgesia or IV opioid analgesia, with both groups receiving postoperative epidural analgesia (Moselli 2011 **Level II**, n=35, JS 3). In the intraoperative epidural group, inflammatory markers were lower up to 24 h postoperatively and minor complications were reduced in number (39 vs 76%), although there was no difference in major complications or LOS. Postoperative ileus is attenuated in patients receiving IV lidocaine infusions compared to saline in patients undergoing colonic surgery (Sun 2012 **Level I** [PRISMA], 21 RCTs, n=1,108; Vigneault 2011 **Level I** [PRISMA], 29 RCTs, n=1,754) (15 RCT overlap). Analgesic and bowel motility benefits of lidocaine were more marked when administered via the thoracic epidural route than by IV infusion (Kuo 2006 **Level II**, n=60, JS 5); however, both lidocaine groups were associated with reduced opioid consumption compared with saline. The postoperative decreases in proinflammatory cytokines, such as interleukin (IL)-6, IL-8 and IL-1RA (a competitive inhibitor of IL-1β), were associated with more rapid return of bowel function following abdominal surgery. Ketamine, administered intraoperatively, is associated with reduced IL-6 levels post operatively, suggesting an anti-inflammatory effect in addition to analgesic benefits (Dale 2012 **Level I** [PRISMA], 6 RCTs, n=331).

In addition to the stress responses to surgery and analgesia, aberrant neuronal firing during acute pain creates a state of altered cell function in nociceptive pathways. This may not be perceived as pain by higher brain centres (eg under general anaesthesia) nor acknowledged consciously by the individual. Cellular adaptations to acute nociceptive inputs in primary and secondary fibres are well established to drive peripheral and central sensitisation (Baron 2013 **NR**; von Hehn 2012 **NR**; Woolf 2011 **NR**; Kuner 2010 **NR**). Critically, these result in multiple changes to gene transcription and protein translation (see also Section 1.1).

1.6.2 | Adverse physiological effects

Clinically significant injury responses that are often associated with nociceptive stimuli trigger diffuse physiological responses such as stress and inflammation, which leads to hyperalgesia, hyperglycaemia, protein catabolism, increased free fatty acid levels (lipolysis) and changes in water and electrolyte flux (Manou-Stathopoulou 2019 **NR**; Carli 2008 **NR**; Liu 2008 **NR**) (see Table 1.5). In addition, increased sympathetic activity has diverse effects on the cardiovascular, gastrointestinal and respiratory systems and on coagulation, endocrine, immune and psychological function (Prabhakar 2014 **NR**; Cardinale 2011 **NR**; Blackburn 2011 **NR**).

Table 1.5 | Metabolic immunological and endocrine responses to injury

Endocrine	↑Catabolic hormones	ACTH, cortisol, ADH, growth hormone, catecholamines, angiotensin II, aldosterone, glucagons,
	↓Anabolic hormones	Insulin, testosterone
Immune	Mitochondrial initiation	Alarmins (DAMP molecules)
	Proinflammatory followed by compensatory response	IL-1, TNFα, IL-6, IL4, IL8, IL10 Chemokines
Metabolic		
Carbohydrate	Hyperglycaemia, glucose intolerance, insulin resistance	Glycogenolysis, gluconeogenesis (cortisol, glucagon, growth hormone, adrenaline, free fatty acids) Insulin secretion/activation
Protein	Muscle protein catabolism, synthesis of acute phase proteins	Cortisol, adrenaline, glucagon, IL-1, IL-6, TNF
Lipid	Lipolysis and oxidation	Catecholamines, cortisol, glucagon, growth hormone
Water and electrolyte flux	Retention of water and sodium, excretion of potassium and functional ECF with shifts to ICF	Catecholamine, aldosterone, ADH, cortisol, angiotensin II, prostaglandins and other factors

Note: *ACTH: adrenocorticotrophic hormone; ADH: antidiuretic hormone; DAMP: damage-associated molecular pattern; ECF: extracellular fluid; ICF: intracellular fluid; IL: interleukin; TNF: tumour necrosis factor.*

Source: *Modified from Manou-Stathopoulou 2019; NHMRC 1999.*

1.6.3 | Pain and analgesia: effects on injury-induced organ dysfunction

Pain from injury activates a range of adverse physiological effects (Manou-Stathopoulou 2019 **NR**; Prabhakar 2014 **NR**; Cardinale 2011 **NR**; Blackburn 2011 **NR**). Increased sympathetic efferent nerve activity increases heart rate, contractility and blood pressure. As sympathetic activation increases myocardial oxygen demand and reduces myocardial oxygen supply, the risk of cardiac ischaemia, particularly in patients with pre-existing cardiac disease, is increased. Enhanced sympathetic activity can also reduce gastrointestinal motility and contribute to ileus. Perioperative neurocognitive disorders such as postoperative delirium are exacerbated by

under-treated pain and associated factors such as stress and inflammation. In patients with fractured neck of femur, delirium was associated with lack of analgesic use (Thompson 2018 **Level IV**, n=688). In elderly patients, postoperative delirium is decreased with the use of multi-component interventions, which include effective analgesia (Siddiqi 2016 **Level I** [Cochrane], 39 RCTs, n=16,082).

Severe pain after upper abdominal and thoracic surgery contributes to an inability to cough and a reduction in functional residual capacity, resulting in atelectasis and ventilation-perfusion abnormalities, hypoxaemia and an increased incidence of pulmonary complications. The injury response also contributes to a suppression of cellular and humoral immune function and a hypercoagulable state following surgery, both of which can contribute to postoperative complications (Lord 2014 **NR**). Alterations to glucose metabolism and accelerated protein breakdown also contribute to the injury response. These factors need to be considered when evaluating analgesic interventions. Patients at greatest risk of adverse outcomes from unrelieved acute pain include very young or elderly patients, those with concurrent medical illnesses and those undergoing major surgery (Liu 2008 **NR**). Analgesic technique may reduce adverse physiological impact and improve surgical outcomes. Often a multimodal approach to anaesthesia, pain management, the surgical stress response and perioperative care is undertaken, making it difficult to separate individual factors involved in outcome; especially with multifaceted strategies such as with enhanced recovery after surgery (ERAS) protocols (Kehlet 2018 **NR**). The influence of epidural anaesthesia and analgesia on outcome has been evaluated (Popping 2014 **Level I** [PRISMA], 125 RCTs, n=9,044) (see also Section 5.6).

There is also limited evidence that stress and opioid analgesia in some circumstances may inhibit immune function, promoting tumour growth or metastasis. Regional anaesthetic and opioid-sparing analgesic techniques might have a beneficial effect on rates of cancer recurrence after tumour resection but overall study results are still unclear (Meserve 2014 **NR**; Colvin 2012 **NR**).

KEY MESSAGES

1. Recognition of the importance of postoperative rehabilitation including pharmacological, physical, psychological and nutritional components has led to enhanced recovery (**U**) (**Level I** [PRISMA]).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Acute pain and injury of various types are inevitably interrelated and, if severe and prolonged, the injury response becomes counterproductive and can have adverse effects on outcome (**U**).

1.6.4 | Adverse psychological effects

Psychological changes associated with acute pain have received less clinical attention than those associated with chronic pain, however they have been well-studied in experimental contexts, especially regarding interference with attention and cognitive processes such as learning and memory. Clinically, sustained acute nociceptive input, as often occurs after surgery, trauma or burns, can also have a major influence on psychological function, which may in turn increase the risk of progression to chronic pain (Glare 2019 **NR**). In addition, pre-operative psychological characteristics, in concert with other factors (eg genetic factors and pre-operative pain), have

also been found predictive of adverse reactions to postoperative pain (Yang 2019 **Level III-2 SR**, 33 studies, n=53,362; Lindberg 2017 **Level IV**, n=188; Schug 2017 **NR**).

Failure to relieve acute pain may result in increasing anxiety, inability to sleep, demoralisation, a feeling of helplessness, loss of control, and an inability to think and interact with others; in the most extreme situations, where patients can no longer communicate, effectively they have lost their autonomy (VanDenKerkhof 2012b **Level IV**, n=76; Cousins 2004 **NR**). In turn, these psychological responses in the acute phase may be major determinants of progression to chronic pain conditions, such as chronic postsurgical pain (CPSP), typically in combination with other known risk factors (Jenewein 2009 **Level III-2**, n=90; Williamson 2009 **Level III-2**, n=1,290; Schug 2017 **NR**; Young Casey 2008 **NR**). In breast cancer surgery patients, anxiety and low psychological robustness (positive affect and dispositional optimism) emerged as significant predictors of acute pain with distress being the strongest predictor of chronic pain (McCowat 2019 **Level IV SR**, 12 studies, n=3,452). However, the relationship between depression and CPSP was uncertain

In acute pain, attention has also focussed on perioperative neurocognitive disorders (PND), including delirium and the research outcome of postoperative cognitive dysfunction (POCD). Both pain itself and analgesic drugs can exacerbate PND, especially delirium (Scottish Intercollegiate Guidelines Network 2019 **GL**). Although the aetiology of PND (and POCD) is unclear, factors include dysregulation of cerebral neurotransmitters, patient factors (age, preoperative cognitive function), and perioperative pharmacological therapy (Evered 2018 **NR**). Neurotransmitters involved in PND include acetylcholine and serotonin, especially in the elderly (Inouye 2014 **NR**); hence analgesics and adjuvants with anticholinergic or sedative effects should be avoided where possible in at-risk patients (Scottish Intercollegiate Guidelines Network 2019 **GL**; American Geriatrics Society 2015 **GL**). Effective non-opioid-based acute pain management in older patients helps reduce delirium (Scottish Intercollegiate Guidelines Network 2019 **GL**; Mahanna-Gabrielli 2019 **NR**) (see also Sections 1.2, 1.4, 9.2).

KEY MESSAGES

1. Postoperative delirium is exacerbated by unrelieved acute pain and by overuse of sedating analgesics, in particular opioids (**N**) (**Level IV**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Failure to relieve acute pain can lead to psychological distress (**N**).

1.7 | Genetics and acute pain

An increasing number of genetic variants modulating nociception, susceptibility to pain conditions, as well as response to pharmacotherapy are being discovered.

Pharmacogenomics deals with the influence of variations in the human genome on response (both beneficial and undesirable) to medicines in patients. By correlating gene alterations with a medicine's efficacy or toxicity, it is possible to gain a better understanding of the causes of interpatient variability in response to a specific medicine and so to develop a rational means to optimise pharmacological therapy with respect to the patient's genotype and ensure maximum efficacy with minimal adverse effects. For example, genetic factors regulating opioid pharmacokinetics (metabolising enzymes, transporters) and pharmacodynamics (receptors and signal transduction elements, ion channels, enzymes) contribute to the large interpatient variability in postoperative opioid requirements (De Gregori 2016 **NR**; Trescot 2014 **NR**). Information from genotyping may help in selecting the analgesic medicine and the dosing regimen for an individual patient (Packiasabapathy 2018 **NR**; Allegri 2010 **NR;** Lotsch 2006 **NR**). Nevertheless, given the complexity of pain pathways, in very few cases is a single gene variant contributing substantially to response variability, but rather there are a large number of small contributions from multiple genes.

Although there is increasing information from studies, often small numbers of subjects are involved and therefore translation into clinical practice is still limited (Trescot 2014 **NR**; Stamer 2007b **NR**). Nevertheless, some preliminary estimates for dose adaptations are possible (Allegri 2010 **NR**; Lotsch 2006 **NR**). Importantly however, genetic factors must be considered within the context of the multiple interacting physiological, psychological, age-related, cultural, ethnic and environmental factors that influence individual responses to pain and analgesia (Sadhasivam 2014 **NR**; Searle 2009a **NR**; Kim 2009 **NR**).

1.7.1 | Single gene pain disorders

A number of rare pain-related conditions have been identified through family linkage mapping, which are due to single gene mutations (Mendelian gene).

Recognised hereditary syndromes associated with reduced pain sensation include the following.

- Channelopathy-associated insensitivity to pain (CAIP) is caused by variants in the *SCN9A* gene, which codes for the alpha-subunit of the voltage-gated sodium channel $Na_v1.7$. $Na_v1.7$ is located in peripheral (dorsal root and sympathetic ganglion) neurones and plays an important role in action potential generation in these cells. Mutations that result in loss of $Na_v1.7$ function cause affected individuals to be unable to feel physical pain (Bennett 2014 **NR**). Patients with a single-nucleotide polymorphism (SNP) in *SCN9A* (3312T; 5.5% frequency) had lower postoperative pain sensitivity after pancreatectomy, lower PCA requirements and a lower likelihood of developing inadequate analgesia than those carrying the 3312G allele (OR 0.10; 95%CI 0.01 to 0.76) (Duan 2013 **Level III-2**, n=200).
- Hereditary sensory and autonomic neuropathy (HSAN) I–V syndromes are associated with a range of genetic abnormalities and produce varying patterns of sensory and autonomic dysfunction and peripheral neuropathy (NTRK1 gene) (Vetter 2017 **NR**; Auer-Grumbach 2013 **NR**; Mogil 2012 **NR**). These syndromes present as various combinations of loss or reduced sensitivity to pain accompanied by other autonomic and sensory deficits. HSAN type IV is also known as congenital insensitivity to pain with anhydrosis (CIPA).

Recognised hereditary syndromes associated with increased pain sensation include (Mogil 2012 **NR**):

- Erythromelalgia and paroxysmal extreme pain disorder, also known as familial rectal disorder, both of which are due to different gain-of-function mutations of sodium channel Nav1.7 (SCN9A) (Dabby 2012 **NR**);
- Familial hemiplegic migraine;
- Hereditary neuralgic amyotrophy;
- Hereditary pancreatitis (Rebours 2012 **NR**).

1.7.2 | Genetic influences on sensitivity to pain

Apart from these rare Mendelian inherited conditions, "pain sensitivity" variability is thought to vary up to 50% in the general population due to genetic differences, with environmental influences responsible for the remainder of variability (Norbury 2007 **Level IV**, n=196). Twin studies have helped identify inheritable traits for development of back pain, postherpetic neuralgia, fibromyalgia and other common painful conditions (Mogil 2012 **NR**).

While several hundred genes have been identified as associated with pain expression in mice, they are not necessarily relevant to humans (LaCroix-Fralish 2011 **SR BS**) and have been studied in chronic and not acute pain (Kringel 2018 **Level IV**; Zorina-Lichtenwalter 2016 **NR**). Evidence for a genetic association with more common pain conditions has come from association studies, which require large cohorts (Mogil 2012 **NR**). Studies often suffer from low sample sizes and the restricted number of potential genotype variants studied. Many findings of an association of a particular gene allele with pain sensitivity have not been replicated in subsequent studies, so caution is needed in this area.

Many genetic variants have been associated with pain sensitivity (Crist 2014 **NR**); the most commonly studied genes include:

- Mu opioid receptor (*OPRM1*);
- Catechol-O-methyltransferase (*COMT*);
- Guanosine triphosphate cyclohydrolase 1;
- Transient receptor potential (*TRPV1*);
- Melanocortin-1 receptor (*MC1R*).

Other gene variants that have been associated with alterations in pain sensitivity in acute pain states include *ADRB2, HTR2A, IL1RN, KCNJ6, MAOA* and *MAOB* (Mogil 2012 **NR),** *P2RX7* (Kambur 2018 **Level III-2**, n=3,847) and *TAOK3* (Cook-Sather 2014 **Level III-2**, n=617). Often studies have addressed postoperative analgesic requirements as the index of pain sensitivity rather than use of experimental pain models.

1.7.2.1 | OPRM1

A variant of the gene encoding the mu opioid receptor *OPRM1,* A118G SNP, was targeted as a very promising candidate for modulation of analgesia and has been the most studied variant (Crist 2014 **NR**).

Overall findings on the effects of this SNP remain contradictory (Crist 2014 **NR**). In a random-effects meta-analysis in the postoperative setting, *OPRM1* 118G-allele carriers have higher mean opioid requirements than *OPRM1* 118AA homozygotes (SMD -0.18; p=0.003) (Hwang 2014 **Level III-2 SR**, 18 studies, n=4,607). These findings were robust in a subgroup analysis of Asian patients, whose frequency of the G variant is about 40% compared to about 15% for Caucasians (SMD -0.21; p=0.001), morphine users (SMD -0.29; p<0.001) and patients after bowel surgery (SMD -0.20; p=0.008). A preceding systematic review found a similar but smaller effect (SMD 0.096;

95%CI 0.025 to 0.167) of *OPRM1* 118G with increased opioid requirements in the perioperative and postoperative period (Walter 2013 **Level III-2 SR**, 14 studies, n=3,346); there was no significant association of *OPRM1* 118G with opioid requirements, when using the random-effects environment (Cohen's d 0.044; 95%CI -0.113 to 0.202). A positive finding was obtained in 1,000 women undergoing breast cancer surgery in which the GG cohort required about 33% more oxycodone than the AA cohort (Cajanus 2014 **Level III-2 SR**, n=1,000). For epidural analgesia using fentanyl during labour however, G-allele (AG+GG) carriers of the *OPRM1* 118 polymorphism required lower (not higher) fentanyl doses to achieve adequate pain relief compared to those with the AA homozygote (SMD -0.24; 95%CI -0.44 to -0.03) (Song 2013 **Level III-2 SR**, 6 studies, n=838). *OPRM1* 304A/G polymorphism did not influence the duration of effect or the requirement for breakthrough analgesia after intrathecal (IT) opioid administration for labour pain (Wong 2010 **Level III-2**, n=293). There was also no effect of A118G mu-opioid receptor polymorphism on duration of analgesia found in a subsequent study, but patients of Hispanic/African origin had increased duration of analgesia and pruritus vs Jewish/Arabic patients in labour (Ginosar 2013 **Level III-2**, n=125).

OPRM1 A118G seems to modulate effects of opioids given in experimental pain; in the clinical setting it has limited impact with no clinical relevance in Caucasians, but explains increased opioid requirements in Asians. Studies that assessed different haplotypes of the *OPRM1* and combinations of genetic variants, eg *OPRM1*, COMT and ESR1, found greater predictability suggesting more complexity (De Gregori 2016 **Level III-2**, n=201; Reyes-Gibby 2007 **Level III-2**, n=207; Mura 2013 **NR**). Overall *OPRM1* 118 polymorphisms may be too complex to be used as a predictive tool for individual opioid dosing (Mogil 2012 **NR**).

1.7.2.2 | COMT

COMT metabolises noradrenaline, adrenaline, and dopamine and has been implicated in the modulation of pain. COMT inhibition or low activity via genetic polymorphisms may lead to increased pain sensitivity via beta-adrenergic receptor-dependent mechanisms (Nackley 2007 **NR**). Haplotypes with high COMT activity are associated with low pain sensitivity to mechanical and thermal stimuli (Diatchenko 2005 **NR**). The Val158Met polymorphism influences the activity of the COMT enzyme with the Met158 allele associated with low COMT activity and increased pain sensitivity (Vuilleumier 2012 **NR**), leading to greater morphine requirements post-surgery in adults (Dai 2010 **Level IV**, n=69) and children (Sadhasivam 2014 **Level IV**, n=149).

A large study undertaken to address influence of *COMT* polymorphism on postoperative pain in a homogenous ethnic sample of 1,000 women having breast surgery showed no association with any *COMT* polymorphism and postoperative oxycodone requirements (Kambur 2013 **Level III-2**, n=1,000). Furthermore, the most studied *COMT* mutation, Val158Met, showed no association with pain levels in these patients, but two previously unstudied mutations did. In contrast, in 152 patients undergoing nephrectomy, the 31 patients with Val/Val genotype consumed more IV morphine than 61 Met/Met patients (36%; 95%CI 31 to 41) (Candiotti 2014 **Level III-2**, n=152). Combinations of several genetic mutations act together to determine pain sensitivity associated with COMT (Smith 2014 **Level III-2**, n=398). Similarly, genetic association studies using COMT variants have also revealed conflicting results (Belfer 2011 **NR**).

1.7.2.3 | TRPA1

Emerging evidence suggests that epigenetic variations of the TRPA1 receptor may be responsible for some of the genetically determined individual differences in pain sensitivity (Gombert 2017 **Level III-2 EH**, n=75; Bell 2014 **Level III-2 EH**, n=100).

There is considerable complexity associated with genetic mutations influencing pain sensitivity and much to be unravelled before clear evidenced-based conclusions can be drawn.

1.7.3 | Drug metabolism

Drug-metabolising enzymes represent a major target for identifying associations between an individual's genetic profile and drug response (pharmacogenetics) (Trescot 2014 **NR**; Stamer 2007c **NR**). The polymorphic cytochrome P450 enzymes metabolise most medicines and show interindividual variability in their catalytic activity. There are 57 enzymes in this family of which 9 are clinically relevant to drug metabolism: CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4/3A5, all of which have different and often overlapping activity. Medicines can be substrates, inhibitors or inducers of metabolism of analgesic medications.

CYP2D6, CYP2C19, and CYP2C9 are highly polymorphic and are involved in approximately 40% of CYP-mediated drug metabolism. Of these, CYP2D6 is the most relevant to analgesic medications. Those who have the genetic variants resulting in poor metabolism by CYP2D6 are likely to have more severe postoperative pain than those who have other variants (Yang 2012 **Level III-2**, n=236).

CYP2D6 gene influences the metabolism of many medications including codeine, tramadol, oxycodone, hydrocodone, dextromethorphan, amitriptyline, nortriptyline, duloxetine, metoclopramide and venlafaxine. Specifically, CYP2D6 metabolises codeine, dihydrocodeine, hydrocodone, oxycodone and tramadol to their more potent hydroxyl metabolites, which have a higher affinity for the mu receptor (Somogyi 2007 **NR**). For additional detail related to individual opioids see Section 4.3.1.

Over 100 allelic variants of *CYP2D6* have been identified, resulting in wide variability in function. Individuals carrying two wild type alleles display normal enzyme activity and are known as normal metabolisers; intermediate metabolisers are heterozygotes with one reduced function and one nonfunctional allele; poor metabolisers have no functionally active alleles and have minimal or no enzyme activity (Crews 2014 **NR**; Vuilleumier 2012 **NR**; Zhou 2009a **NR**; Zhou 2009b **NR**). Ultrarapid metabolisers have multiple copies of the wildtype *CYP2D6* alleles (Crews 2014 **NR**; Vuilleumier 2012 **NR**; Stamer 2007b **NR**).

There are large interethnic differences in the frequencies of the variant alleles. For example, in Caucasian populations, 8–10% of people are poor metabolisers and 1-3% are ultrarapid metabolisers (Crews 2014 **NR**; Vuilleumier 2012 **NR**; Stamer 2007b **NR**). The proportion of ultrarapid metabolisers is higher (up to 29%) in Middle Eastern and Northern African populations and lower (0.5%) in Asian populations (Stamer 2007c **NR**). The proportion of poor metabolisers is lower in Asian and African American populations (Zhou 2017 **Level IV SR**, 5 population-scale sequencing projects, n=56,945; Yee 2013 **Level IV**, n=75; Holmquist 2009 **NR**).

Other genetic factors indirectly affecting the metabolism or effect of analgesics are liver cell transporter proteins: organic cation transporter (OCT1) (Fukuda 2013 **Level III-2**, n=146); ABCC3 (Venkatasubramanian 2014 **Level III-2**, n=220) and ATP-binding cassette subfamily member B1 (also known as multidrug resistance protein [MDR]1 or p-glycoprotein) (Sadhasivam 2015 **Level III-2**, n=263). The latter affects efflux transport of morphine at the blood-brain barrier and thereby cerebral pharmacokinetics.

Further considerations are the differential risk with genetic differences and varying prevalence of racial/ethnic phenotypes (Anderson 2014 **NR**) and consequent variability in sensitivity to efficacy and adverse effects (Jimenez 2012 **Level III-3**, n=68**;** Fukuda 2013 **Level IV**, n=146**;** Palada 2018 **NR**).

1.7.3.1 | Codeine and CYP2D6

In children and adults receiving codeine for postoperative pain, very low or undetectable plasma morphine levels have been noted in those with poor metaboliser or intermediate metaboliser genotypes, but with variable impact on analgesia (Williams 2002 **Level II**, n=96, JS 3; Poulsen 1998 **Level IV**, n=81; Persson 1995 **Level IV**, n=11).

CYP2D6 genotypes predicting ultrarapid metabolism resulted in about 50% higher plasma morphine and its glucuronides concentrations following oral codeine compared with the extensive metaboliser (Kirchheiner 2007 **Level IV**). Both the impaired renal clearance of these metabolites and genetic background (CYP2D6 ultrarapid metaboliser status) have been implicated in reports of respiratory depression due to codeine in adults and children (Friedrichsdorf 2013 **Level IV**; Kelly 2012 **Level IV**; Stamer 2007b **Level IV**). (See also Sections 4.3.1.3 and 10.4.4.5)

1.7.3.2 | Tramadol and CYP2D6

O-demethylation of tramadol by the enzyme CYP2D6 produces the active metabolite (+)-O-demethyltramadol (M1), which has an affinity for mu-opioid receptors that is approximately 200 times higher than the parent drug (Lai 1996 **BS**). Poor metabolisers have significantly lower plasma concentrations of M1 compared with both homozygous and heterozygous extensive metabolisers (Fliegert 2005 **Level II**, n=26, JS 2; Kirchheiner 2008 **Level III-2**, n=22; Stamer 2003 **Level III-3**, n=300) and experience less analgesia (Stamer 2007a **Level III-3**, n=174; Stamer 2003 **Level III-3**, n=300). As with codeine, impaired renal clearance of metabolites and genetic background (CYP2D6 ultrarapid metaboliser status) have been implicated in cases of respiratory depression after tramadol (Desmeules 1996 **Level II**, n=10, JS 3**;** Stamer 2008 **CR**) (see also Section 4.3.1.3).

1.7.3.3 | Methadone

Genetic polymorphisms in genes coding for methadone-metabolising enzymes, transporter proteins (p-glycoprotein) and mu-opioid receptors may explain part of the observed interindividual variation in the pharmacokinetics and pharmacodynamics of methadone; blood concentrations may vary up to 20-fold for a given dose (Somogyi 2014 **NR**; Li 2008 **NR**).

Methadone is metabolised primarily by CYP2B6 and to a minor extent by CYP3A4 (Kharasch 2017 **NR**; Kapur 2011 **NR**). Differing effects for isomers of methadone have also been reported; genetic variability in CYP2B6 influenced (S)-methadone (less active isomer) and, to a lesser extent, (R)-methadone (more active isomer) plasma concentrations (Somogyi 2014 **NR**). In addition, genetic polymorphisms in *CYP2C19* gene (responsible for a minor role in methadone metabolism) have effects on methadone-maintenance dosing, (R)-methadone/methadone ratio and cardiotoxicity of methadone (prolonged QT interval) (Wang 2013 **NR**) (see also Section 4.3.1.5).

1.7.3.4 | Oxycodone

Oxycodone is metabolised primarily to noroxycodone by CYP3A4 (≈80%) and by CYP2D6 to oxymorphone (Lalovic 2006 **Level IV EH**). The O-demethylated metabolite oxymorphone has up to 40-fold higher affinity for the mu receptor and eight-fold higher potency than oxycodone and represents about 11% of its overall metabolism (Crews 2014 **NR**). Oxymorphone may contribute significantly to the overall analgesic effect of oxycodone in experimental pain (Samer 2010 **EH**); noroxycodone, the major metabolite, is only a weak mu-receptor agonist (Lalovic 2006 **EH**; Coluzzi 2005 **NR**).

The dependence of oxymorphone concentrations on CYP2D6 activity and its high potency explains why oxycodone's pharmacodynamics and pharmacokinetics are dependent on *CYP2D6* polymorphism (Soderberg Lofdal 2013 **NR**), at least in experimental pain (Samer 2010 **EH**).

However, in acute postoperative pain, *CYP2D6* genotype had either no influence on oxycodone requirements (Zwisler 2010 **Level III-2**, n=270) or a small difference in dosage that was not gene-dose related (Stamer 2013 **Level III-2**, n=121). Overall, the data on the association of *CYP2D6* pheno/genotype and oxycodone response in acute pain are unconvincing (Huddart 2018 **NR**) (see also Section 4.3.1.2).

1.7.3.5 | NSAIDs

Wide variability in gene expression and functional polymorphisms in the COX-2 gene (*PTGS2*) may explain part of the interindividual variations in acute pain and the analgesic efficacy of nsNSAIDs and coxibs; this may be useful to predict patient risk and benefit from medicines based on individual genetic variations (Somogyi 2007 **NR**; Lee 2006 **Level III-2**).

NSAIDs such as ibuprofen, diclofenac and celecoxib are metabolised by CYP2C9 (Rollason 2014 **NR**). Between 1 and 3% of Caucasians are poor metabolisers. Homozygous carriers of the *CYP2C9*3* allele may accumulate celecoxib and ibuprofen in blood and tissues and be at risk of increased adverse effects (Kirchheiner 2003 **Level III-3**, n=26; Kirchheiner 2002 **Level IV**; Rollason 2014 **NR**; Stamer 2007b **NR**), but this is unlikely to affect acute pain response.

KEY MESSAGES

1. CYP2D6 polymorphisms affect plasma concentrations of active metabolites of codeine, oxycodone and tramadol with variable effects on analgesic efficacy (**U**) (**Level II**).
2. The mu opioid receptor OPRM1 polymorphism is unlikely to be clinically relevant as a single gene mutation in Caucasian populations and is more likely to be of clinical relevance in Asian populations (**U**) (**Level III-2 SR**).
3. CYP2D6 ultrarapid metabolisers are at increased risk of codeine and tramadol toxicity (**U**) (**Level IV**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Genetic polymorphisms contribute to the wide interindividual variability in plasma concentrations of a given dose of methadone (**U**).

2.0 | Assessment and measurement of pain and pain treatment

Reliable and accurate assessment of acute pain is necessary to ensure safe and effective pain management and to provide effective research outcome data. The assessment and measurement of pain is fundamental to the process of assisting in the diagnosis of the cause of a patient's pain, selecting an appropriate analgesic therapy and evaluating then modifying that therapy according to the individual patient's response. Pain should be assessed within a sociopsychobiomedical model that recognises that physiological, psychological and environmental factors influence the overall pain experience. Likewise, the decision regarding the appropriate intervention following assessment needs to be made with regard to a number of factors, including recent therapy, potential risks and side effects, any management plan for the particular patient and the patient's own preferences. A given pain 'rating' should not automatically trigger a specific intervention without such considerations being undertaken (van Dijk 2012a **Level IV**, n=2,674; van Dijk 2012b **Level IV**, n=10,434). Care must be undertaken with pain assessment to avoid the process of assessment itself acting as a nocebo (see Section 1.3).

2.1 | Assessment

The assessment of acute pain should include a thorough general medical history and physical examination, a specific "pain history" (see Table 2.1) and an evaluation of associated functional impairment (see Section 2.3). In acute pain management, assessment must be undertaken at appropriate frequent intervals. At these times, evaluation of pain intensity, functional impact and adverse effects of treatment must be undertaken and recorded using tools and scales that are consistent, valid and reliable (Scott 2008 **NR**). In addition, pain assessment must lead to changes in management and re-evaluation of the patient to ensure improvements in the quality of care (Gordon 2005 **GL**).

Although not always possible in an acute setting, a complete pain history provides important diagnostic information that may help distinguish different underlying pain states such as nociceptive (somatic and visceral) or neuropathic pain (Victor 2008 **Level III-2**, n=823). Somatic pain may be described as sharp, hot or stinging, is generally well localised and is associated with local and surrounding tenderness. By contrast, visceral pain may be described as dull, cramping or colicky, is often poorly localised and may be associated with tenderness locally or in the area of referred pain, or with symptoms such as nausea, sweating and cardiovascular changes (Scott 2008 **NR**).

While nociceptive pain typically predominates in the acute pain setting, neuropathic pain may also be present (Guastella 2011 **Level IV**, n=54) (see also Section 1.1 and 8.1.4). Features in the pain history that may suggest a diagnosis of neuropathic pain include (Dworkin 2007 **Level III-2**, n=618; Haanpaa 2011 **GL**; Gray 2008 **NR**):

- Clinical circumstances associated with a high risk of nerve injury (eg thoracic or chest wall procedures, amputations or hernia repairs);
- Pain descriptors such as burning, shooting and stabbing;
- The paroxysmal or spontaneous nature of the pain which may have no clear precipitating factors;
- The presence of dysaesthesias (spontaneous or evoked unpleasant abnormal sensations), hyperalgesia (increased response to a normally painful stimulus), allodynia (pain due to a stimulus that does not normally evoke pain such as light touch) or areas of hypoaesthesia;

- Regional autonomic features (changes in colour, temperature and sweating) and phantom phenomena.

The IASP definition of neuropathic pain is "*pain caused by a lesion or disease of the somatosensory system*" (IASP 2019 **GL**; Jensen 2011 **NR**). This has been subdivided into 'central' and 'peripheral' neuropathic pain (IASP 2019 **GL**). Symptoms consistent with neuropathic pain may occur without nerve injury (nociplastic pain) (IASP 2019 **GL**; Kosek 2016 **NR**). To determine if pain is neuropathic, further quantitative sensory testing (QST) may be needed (Haanpaa 2011 **GL**; Garcia-Larrea 2012 **NR**).

It is useful to draw the distinction between the different types of pain because the likely duration of the pain and the response to analgesic strategies may vary. The concept of "*mechanism-based pain diagnosis*" has been promoted (Woolf 2001 **NR**) and although the correlation between symptoms, mechanisms and response to therapy is not fully defined, specific therapy targeted at, for example neuropathic pain, may be of benefit (Gray 2008 **NR**).

Table 2.1 | Fundamentals of a pain history (not necessarily applicable to all settings of acute pain)

1 Site of pain a. primary location: description ± body map diagram b. radiation
2 Circumstances associated with pain onset including details of trauma or surgical procedures
3 Character of pain a. sensory descriptors eg sharp, throbbing, aching (Victor 2008) b. McGill Pain Questionnaire: includes sensory and affective descriptors (Melzack 1987) c. neuropathic pain characteristics (eg NPQ; DN4; LANSS; PainDETECT; ID Pain)
4 Intensity of pain a. at rest b. on movement c. temporal factors i duration ii current pain, during last week, highest and lowest level iii continuous or intermittent d. aggravating or relieving factors
5 Associated symptoms (eg nausea)
6 Effect of pain on activities and sleep a. Functional assessment tools i Acute (eg Functional Activity Scale) ii Recent (eg Brief Pain Inventory – Short Form (BPI-SF))
7 Treatment a. current and previous medications — dose, frequency of use, efficacy, adverse effects b. other treatment eg transcutaneous electrical nerve stimulation c. health professionals consulted

8 Relevant medical history

a. prior or coexisting pain conditions and treatment outcomes
b. prior or coexisting medical conditions

9 Factors influencing the patient's symptomatic treatment

a. belief concerning the causes of pain
b. knowledge, expectations and preferences for pain management
c. expectations of outcome of pain treatment
d. reduction in pain required for patient satisfaction or to resume "reasonable activities"
e. typical coping response for stress or pain, including presence of anxiety or psychiatric disorders (eg depression or psychosis)
f. family/cultural expectations and beliefs about pain, stress and postoperative course

Notes: *NPQ - Neuropathic Pain Questionnaire; DN4 - Douleur Neuropathique en 4; LANSS - Leeds Assessment of Neuropathic Symptoms and Signs.*

2.2 | Measurement

The definition of pain underlies the complexity of its measurement. As described in Chapter 1, pain is an individual and subjective experience modulated by physiological, psychological and environmental factors such as previous events, culture, prognosis, coping strategies, fear and anxiety. Therefore, most measures of pain are based on self-report. These measures lead to sensitive and consistent results if administered properly (Moore 2003 **NR**). Self-report measures may be influenced by mood, sleep disturbance and medications (Scott 2008 **NR**).

In some instances, it may not be possible to obtain reliable self-reports of pain eg patients with impaired consciousness or cognitive impairment, young children (see Section 10.3), elderly patients (see Section 9.2) or where there are failures of communication due to language difficulties, inability to understand the measures, unwillingness to cooperate or severe anxiety. In these circumstances, other methods of pain assessment will be needed.

There are no objective measures of "pain" but associated factors such as hyperalgesia (eg mechanical withdrawal threshold), the stress response (eg plasma cortisol concentrations), behavioural responses (eg facial expression), functional impairment (eg coughing, ambulation) or physiological responses (eg changes in heart rate) may provide additional information. Analgesic requirements (eg patient-controlled opioid doses delivered) are commonly used as *post hoc* measures of pain experienced (Moore 2003 **NR**).

Regular and repeated measurements of pain and its impact should be made to assess ongoing adequacy of analgesic therapy. An appropriate frequency of reassessment will be determined by the duration and severity of the pain, patient needs and response, and the type of medicine or intervention (Gordon 2005 **GL**). Such measurements should incorporate different components of pain, and assessment for analgesic side effects, especially sedation (Macintyre 2011 **NR**). For example, in the postoperative patient this should include assessments of static (rest) and dynamic (on sitting, coughing or moving the affected part) pain. Whereas static measures may relate to the patient's ability to sleep, dynamic measures can provide a simple test for mechanical hyperalgesia and determine whether analgesia is adequate for recovery of function (Breivik 2008 **NR**).

Recording pain intensity as "*the fifth vital sign*" was a program advocated by the USA Department of Veteran Affairs, which aimed to increase awareness and utilisation of pain

assessment (Mularski 2006 **Level III-3**, n=600), with the intention of leading to improved acute pain management (Gould 1992 **Level III-3**, n=2,035). However, an over-reliance on sometimes unrealistic aims (such as "pain free") and an excessive use of opioids is leading to a more moderate and balanced approach to intervention (Levy 2018 **NR**).

Aiming to reduce suffering and improve function rather than targeting 'zero pain' is more in keeping with patient expectations (Lee 2016 **NR**). In 2018, the USA Joint Commission (JCAHO) implemented new and revised pain assessment and management standards for accredited hospitals, emphasising patient engagement, multimodal therapy and improving pain assessment by concentrating more on how pain affects patients' physical function (JCAHO 2017 **GL**).

Uncontrollable or escalating pain should always trigger a reassessment of the diagnosis and consideration of alternatives such as developing surgical or other complications, or the presence of neuropathic pain. Review by an acute pain service (APS) or other specialist group should be considered.

2.2.1 | Unidimensional measures of pain

A number of scales are available that measure either pain intensity or the degree of pain relief following an intervention. Pain relief scales, although less commonly used, have some advantage when comparing the response to different treatments as all patients start with the same baseline "relief" score (zero), whereas they may have differing levels of baseline pain intensity (Breivik 2008 **NR**; Moore 2003 **NR**).

2.2.1.1 | Categorical scales

Categorical scales use words to describe the magnitude of pain or the degree of pain relief (Moore 2003 **NR**). The verbal descriptor scale (VDS) is the most common example (eg using terms such as none, mild, moderate, severe and excruciating or agonising) typically using four or five graded descriptors.

These terms can then be converted to numeric scores (eg 0, 2, 5, 8, 10) for charting and easy comparison over time. There is a good correlation between descriptive verbal categories and visual analogue scales (VAS) (Banos 1989 **Level III-2**, n=212), but the VDS is a less sensitive measure of pain treatment outcome than the VAS (Jensen 2002 **Level IV**, n=247). Pain "relief" may also be graded as none, mild, moderate or complete using a VDS.

Categorical scales have the advantage of being quick and simple and may be useful in the elderly or visually impaired patient and in some children. However, the limited number of choices in categorical compared with numerical scales may make it more difficult to detect differences between treatments (Breivik 2000 **Level III-2**). Other limitations include personal, cultural or linguistic differences in interpretation of the specific words chosen as descriptors both between patients and between patients and their clinicians.

2.2.1.2 | Numerical rating scales

Numerical rating scales (NRS) have both written and verbal forms. Patients rate their pain intensity on the scale of zero to ten where zero represents "no pain" and ten represents "worst pain imaginable". The Verbal NRS (VNRS) is typically administered using a phrase such as: "On a scale of zero to ten, with zero being no pain at all and ten being the worst pain you could imagine, where would you rate the pain you are experiencing right now?". VNRS are often preferred because they are simpler to administer, give consistent results and correlate well with the VAS (Karcioglu 2018 **Level I**, 19 RCTs, n=853; Hjermstad 2011 **Level IV SR**, 54 studies, n unspecified; Safikhani 2018 **NR**). Recall of pain intensity using the VNRS over the previous 24 h was a reasonable

indicator of average pain experienced by the patient during that time (Jensen 2008 **Level III-2**). VNRS may reflect pain interference as well as pain intensity (Thong 2018 **Level III-3**, n=101; Jensen 2017 **Level IV**, n=807).

It is important that scales are consistent, and it is recommended that the "no pain" point be represented as zero rather than one (Scott 2008 **NR**). Pain relief may be measured in the reverse direction with zero representing "no relief" to ten representing "complete relief". A visual form of the 11-point NRS with tick marks on a line or boxes with numbers may also be used (Breivik 2008 **NR**). Although NRS are widely used, some patients have difficulty representing their pain in numerical terms and are better suited to a categorical scale. A value of four or more is often used as a threshold to guide clinical intervention (Hartrick 2003 **Level IV**, n=222).

2.2.1.3 | Visual analogue scales

Visual analogue scales (VAS) consist of a 100 mm horizontal line with verbal anchors at both ends and no tick marks. The patient is asked to mark the line and the "score" is the distance in millimetres from the left side of the scale to the mark. VAS are the most commonly used scales for rating pain intensity in research, with the words "no pain" at the left end and "worst pain imaginable" at the right. Pictorial versions also exist. VAS can also be used to measure other aspects of the pain experience (eg affective components, patient satisfaction, adverse effects).

Assessment of pain immediately after surgery can be more difficult and lead to greater interpatient variability in pain scores because of transient anaesthetic-related cognitive impairment and decreases in visual acuity. A "pain meter" (PAULA), which used five coloured emoticon faces on the front of a ruler and corresponding VAS scores on the back and allowed patients to move a slider to mark the pain they were experiencing, resulted in less variance than pain scores obtained from a standard VAS (Machata 2009 **Level III-2**, n=48).

VAS ratings ≥70 mm are indicative of "severe pain" (Aubrun 2003 **Level IV**, n=3,045; Jensen 2003 **Level IV**, n=248) and 0–5 mm "no pain", 5–44 mm "mild pain" and 45–69 "moderate pain" (Aubrun 2003 **Level IV**, n=3,045). A reduction in pain intensity by 30–35% has been rated as clinically meaningful by patients with postoperative pain (Cepeda 2003 **Level IV**, n=700; Jensen 2003 **Level IV**, n=248), acute pain in the emergency department (ED) (Lee 2003 **Level IV**, n=143), breakthrough cancer pain (Farrar 2000 **Level IV**, n=1,268 [episodes of breakthrough pain]) and chronic pain (Farrar 2001 **Level IV**, n=2,724).

These scales have the advantage of being simple and quick to use, allow for a wide choice of ratings and avoid imprecise descriptive terms (Scott 2008 **NR**). However, the scales require concentration and coordination, need physical devices, are unsuitable for children aged <5 y and may be unsuitable in up to 26% of adult patients (Cook 1999 **NR**).

The VAS has been shown to be a linear scale for patients with postoperative pain of mild to moderate intensity (Myles 1999 **Level IV**, n=52) and severe pain (Myles 2005 **Level IV**, n=22). Therefore, results are equally distributed across the scale, such that the difference in pain between each successive increment is equal.

2.2.2 | Functional impact of acute pain

Analgesia should be titrated to achieve both decreased pain intensity and the ability to undertake appropriate functional activity (Breivik 2008 **NR**). This will enable analgesia to optimise recovery. Most tools for measuring the functional impact of pain are based on chronic pain assessment and therefore are not routinely applicable to the acute pain environment.

Measurement of pain intensity scores on movement or with coughing is a useful guide; however, this reflects the subjective pain experience and not the capacity to undertake the

specific activity. The Functional Activity Scale (FAS) score is a simple three-level ranked categorical score designed to be applied at the point of care (Scott 2008 **NR**). Its fundamental purpose is to assess whether the patient can undertake appropriate activity at their current level of pain control and to act as a trigger for intervention should this not be the case. The patient is asked to perform the activity or is taken through the activity in the case of structured physiotherapy (eg joint mobilisation) or nurse-assisted care (eg ambulation, turned in bed). The ability to complete the activity is then assessed using the FAS as:

A — no limitation	the patient is able to undertake the activity without limitation due to pain (pain intensity score is typically zero to three);
B — mild limitation	the patient is able to undertake the activity but experiences moderate to severe pain (pain intensity score is typically four to ten); and
C — significant limitation	the patient is unable to complete the activity due to pain, or pain treatment-related adverse effects, independent of pain intensity scores.

This score is then used to track effectiveness of analgesia on function and trigger interventions if required. Disadvantages of the FAS score are that it has not been independently validated and clinical staff need to be educated in its application.

A four-level scale (no interference, interference with some vs most activities vs unable to do any activity) has been evaluated against NRS in a pilot study and identified a correlation with NRS in cognitively intact but not impaired patients (Halm 2019 **Level III-2**, n=68).

2.2.3 | Multidimensional measures of pain

Rather than assessing only pain intensity, multidimensional tools provide further information about the characteristics of the pain and its impact on the individual. Examples include the Brief Pain Inventory (BPI), which assesses pain intensity and associated disability (Daut 1983 **Level IV**), and the McGill Pain Questionnaire (MPQ), which assesses the sensory, affective and evaluative dimensions of pain (Melzack 1987 **NR**). The MPQ also exists in a 15-item short-form (SF-MPQ), which is well validated and has a VAS item for pain intensity and a VRS for rating the overall pain experience. The role of the McGill Pain questionnaire (and its Short Form variants) has been reviewed; with a conclusion that, while still useful, it provides little information regarding mechanism, nor the broader social and functional impact of the pain and so should not be used as a single measure to guide research or therapy (Main 2016 **NR**) . The BPI also exists in a short form (BPI-SF and -SF2) which includes functional impact of the pain over the previous 24 h (Dworkin 2009 **Level IV**, n=1,008).

2.2.3.1 | Neuropathic Pain

Neuropathic pain is not easily identified using unidimensional tools such as the VAS (Haanpaa 2011 **GL**). Specific scales have been developed that identify (and/or quantify) descriptive factors specific for neuropathic pain (Dworkin 2007 **Level III-2**, n=618; Bouhassira 2005 **Level III-2**, n=160; Bouhassira 2004 **Level IV**, n=176; Cruccu 2004 **GL**; Freynhagen 2006 **NR**) and may also include sensory examination (Bouhassira 2005 **Level III-2**, n=160; Cruccu 2004 **GL**) and allow evaluation of response to treatment (Bouhassira 2004 **Level IV**, n=176).

Screening tools in common use for identifying neuropathic pain include:

- Leeds Assessment of Neuropathic Symptoms and Signs (LANSS) has five symptom items and two clinical assessment items — a subjective-only form also exists (Bennett 2001 **Level III-3**, n=100);
- Douleur Neuropathique en 4 (DN4) has ten items — seven symptomatic and three from clinical examination (Bouhassira 2005 **Level III-3**, n=160);
- Pain DETECT has nine self-reported items that do not require a clinical examination and gives a likelihood scoring for neuropathic pain (Freynhagen 2006 **NR**); its use has been reviewed in over 300,000 patients (Freynhagen 2016 **NR**)
- Neuropathic Pain Questionnaire (NPQ) comprises twelve items and can be self-reported - a three-item short-form also exists (Krause 2003 **Level III-2**, n=528; Backonja 2003 **NR**);
- ID Pain has six self-reported items (Portenoy 2006 **Level IV**, n=586).

These scales have similar specificity and sensitivity (except for the ID Pain, which has lower values than the others), have mostly been validated and are often available in validated translations in many languages (Haanpaa 2011 **GL**)**.** In assessing the criterion validity and reliability of the above screening questionnaires, the DN4 and NPQ were found to be most suitable for clinical use overall, noting that cross-cultural adaptations had less evidence than the original versions (Mathieson 2015 **Level IV SR**, 37 studies, n unspecified).

Clinical questionnaires for neuropathic pain show that subjective pain assessments are essential for diagnosis and assessment of neuropathic pain, with screening questionnaires being effective at leading to more formal diagnosis (aided by assessment questionnaires), and also are valuable in research (Attal 2018 **NR**).

2.2.3.2 | Global scales and satisfaction

Global scales are designed to measure the effectiveness of overall treatment (see Section 2.3.1). They are more suited to outcome evaluation at the end of treatment than to modifying treatment in the acute stage (Moore 2003 **NR**). Questions such as "*How effective do you think the treatment was?*" recognise that unimodal measures of pain intensity cannot adequately represent all aspects of pain perception.

Satisfaction is often used as a global indicator of outcome; however, patients may report high levels of satisfaction even if they have moderate to severe acute pain (Svensson 2001 **Level IV**, n=191). Satisfaction may also be influenced by preoperative expectations of pain, effectiveness of pain relief, the patient–provider relationship (eg communication by medical and nursing staff), interference with function due to pain and number of opioid-related adverse effects (Jensen 2004 **Level IV**, n=191; Carlson 2003 **Level IV**, n=787; Svensson 2001 **Level IV**, n=191). Although complete absence of pain is not required for patients to report high levels of satisfaction, moderate pain (VAS >50/100) has been associated with dissatisfaction (Jensen 2005 **Level III-2**, n=207).

2.2.4 | Patients with special needs

Validated tools are available for measuring pain in neonates, infants and children but must be both age and developmentally appropriate (see Section 10.3). These include behavioural assessments, pictorial scales (eg faces) and response to treatment. Adult patients who have difficulty communicating their pain (eg patients with cognitive impairment or who are critically unwell in the ED or intensive care unit [ICU]) require special attention as do patients whose language or cultural background differs significantly from that of their health care team. Communication aids and behavioural scales such as the modified Faces, Legs, Activity, Cry and

Consolability (FLACC) scale (Erdek 2004 **Level III-3**) can be particularly useful in these situations (see Section 9.2.3).

NRS are considered the best tool for measurement of pain intensity for adult ICU patients who may be non-verbal, sedated or ventilated. If they are not feasible, then the Behavioural Pain Scale (BPS) or Critical-Care Pain Observation Tool (CPOT) should be used (Varndell 2017 **Level III-3 SR**, 26 studies, n unspecified; Barr 2013 **GL**; Azevedo-Santos 2018 **NR**; Gelinas 2013 **NR**). The CPOT has been validated in neurosurgical patients (Echegaray-Benites 2014 **Level III-3**, n=43) and in different countries (Rijkenberg 2015 **Level III-3**, n=68; Li 2014 **Level III-3**, n=63). The CPOT appears to be more specific for pain than the BPS (Rijkenberg 2015 **Level III-3**, n=68).

In patients with dementia, similar challenges often require the use of non-verbal tools. Overall, in assessing reviews of multiple tools there is limited evidence about the reliability, validity and clinical utility of any specific tool (Lichtner 2014 **Level IV SR**, 23 reviews [28 tools]).

A systematic review of the effect of the use of pain assessment tools in critically ill patients on patient outcomes concluded that it improves pain management, but evidence was too heterogeneous to draw firm conclusions regarding outcomes such as length of mechanical ventilation or ICU stay (Georgiou 2015 **SR Level III-2**, 10 studies, n unspecified)

Surveys in the UK and Netherlands show that pain assessment tools were underutilised in many ICUs (Kemp 2017 **Level IV**, n=750 [patients assessed by 362 UK physicians]; van der Woude 2016 **Level IV**, n=107 [adult ICUs in the Netherlands]) (see also Section 8.10).

KEY MESSAGES

1. There is good correlation between the visual analogue and verbal numerical rating scales (**S**) (**Level I**).
2. Regular assessment of pain leads to improved acute pain management (**U**) (**Level III-3**).
3. Appropriate assessments (including screening tools) are required to determine the presence of neuropathic pain (**N**) (**Level III-2**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

- ☑ Functional outcomes rather than pain scores alone should be used to guide acute pain management, including non-pharmacological approaches (**N**).
- ☑ Self-reporting of pain should be used whenever appropriate as pain is by definition a subjective experience (**U**).
- ☑ The pain measurement tool chosen should be appropriate to the individual patient and the clinical context (eg intensive care, ward, community). Developmental, cognitive, emotional, language and cultural factors should be considered (**U**).
- ☑ Scoring should incorporate different components of pain including the functional capacity of the patient. In the postoperative patient, this should include static (rest) and dynamic (eg pain on sitting, coughing) pain (**U**).
- ☑ Uncontrolled or unexpected pain requires a reassessment of the diagnosis and consideration of alternative causes for the pain (eg new surgical/ medical diagnosis, neuropathic pain) (**U**).

2.3 | Outcome measures in acute pain management

What follows is a brief guide to some of the outcome measures used particularly in the acute pain literature. A comprehensive review is beyond the scope of this document and more detail may be found elsewhere (Breivik 2008 **NR**). Concerns have been raised regarding trial design limitations resulting in type II errors (failure to identify a difference when one truly exists) and recommendations have been made for the design of chronic pain RCTs that include patient numbers, study site and outcome measurements to reduce this problem (Dworkin 2012 **GL**). Similar issues are of relevance to studies in acute pain interventions.

2.3.1 | Outcome measures

2.3.1.1 | Pain

The aim of many clinical trials is to determine whether a medicine or intervention provides adequate pain relief for the majority of participants or is equivalent or noninferior to an existing accepted treatment. This can be achieved by repeated single measures at fixed time points, which may encompass only a proportion of the total illness. When comparison is made with a placebo, a statistically significant result can be achieved with a relatively small number of patients (eg n=40) (Collins 2001 **Level I**, 11 SRs [151 RCTs], n unspecified). The primary outcome is chosen by the researcher and may not be of direct importance to the individual patient, particularly if it relates to only a proportion of the total time he/she was in pain. It is also important to consider that statistically significant differences in pain scores may not reflect clinically significant differences, although these are harder to define (see above).

Data derived from categorical and VAS of pain intensity or relief produce a range of summary outcomes that can be used to assess (Moore 2003 **NR**):

- the degree of analgesic effect:
  - difference between the baseline and post-intervention score of pain intensity or pain relief (summed pain intensity difference [SPID]);
  - the area under the time-analgesic effect curve for a given time (total pain relief [TOTPAR]);
  - dose of rescue analgesic consumption required in a given time period (eg PCA use);
- the time to analgesic effect:
  - the time to onset of analgesic effect;
  - time to maximum reduction in pain intensity or to peak relief;
- the duration of effect:
  - time for pain to return to at least 50% of baseline;
  - time for pain intensity to return to baseline or for pain relief to fall to zero; and
  - time to re-medication/rescue analgesia.

A widely used method of describing the effectiveness of an analgesic intervention is the number needed to treat (NNT). In this setting it is commonly defined as the number of patients that need to be treated to achieve at least 50% pain relief (eg at least 50% maximum TOTPAR) in one patient compared with a placebo over a 4–6 h treatment period (Moore 2003 **NR**). Analysis at other cut-off points (30–70% max TOTPAR) has shown the same relative efficacy of different treatments (McQuay 2003 **NR**).

In acute pain research, using TOTPAR to assess pain relief may be more sensitive to treatment effects than SPID which is assessing intensity (Singla 2015 **Level I** [PRISMA], 45 RCTs, n unspecified).

The validity of this approach as a true method of comparison may be questioned as there is no standardisation of the acute pain model or patient and only single doses of the analgesic agents are used. However, it may sometimes be reasonable to extrapolate estimates of analgesic efficacy from one pain model to another (Barden 2004 **Level I**, 160 RCTs, n=14,410).

The use of supplemental analgesic consumption as an outcome measure has been questioned in situations where pain scores are not similar (McQuay 2008 **Level I**, 18 RCTs, n=1,217).

2.3.1.2 | Physical functioning

Measures of physical functioning quantify many aspects of a patient's life including their ability to sleep, eat, think, deep breathe, cough, mobilise, perform activities of self-care and daily living, undertake their usual vocation and to enjoy leisure activities and sport (Williams 1999 **NR**). In acute pain, this may be measured by pain intensity scores with movement or other functional activity scores (see above).

Global or multidimensional measures of function attempt to combine various abilities or disabilities to derive a summary measure. Scales that employ a large number of items might be comprehensive but risk patient exhaustion or error, while scales with fewer items might be patient friendly but risk becoming insensitive to state or change (Williams 1999 **NR**). These scales have been used in some studies of acute spinal pain and cancer-related pain:

- *Disability scales* — generic scales include the Short Form 36 of Medical Outcomes Study (SF-36), the Sickness Impact Profile (SIP) and Roland & Morris Short SIP (Williams 1999 **NR**);
- *Quality of life (QOL) measures* — these measures are not widely used in acute pain studies, but have relevance for chronic or cancer-related pain (Higginson 1997 **NR**).

Disease-specific measures quantify the impact of a specific pain problem on function and can be used to track changes after an intervention (eg ability to cough after thoracotomy, ability to lift a baby after Caesarean section) (Garratt 2001 **Level IV**, n=187). Generic measures facilitate comparisons among the functional limitations of different conditions and treatments and may have advantages for audit of an APS that includes patients with a range of conditions (Patrick 1989 **NR**).

2.3.1.3 | Emotional functioning

Acute pain is an unpleasant sensory and emotional experience. The unpleasantness of the experience and its meaning for the individual may have short term (anxiety, depression, irritability) and long term (lost confidence or self-efficacy or post-traumatic stress disorder) consequences for the individual's emotional functioning.

2.3.1.4 | Adverse effects

In trials of efficacy, adverse effects are usually considered to be of secondary importance and inadequate reporting has been found in as many as half of randomised trials reviewed (Ioannidis 2001 **Level I**, 192 RCTs, n=130,074; Edwards 1999 **Level I**, 52 RCTs, n unspecified). If adverse effects are sufficiently common (eg nausea with opioids), they may be quantifiable in trials of efficacy and specifically measured using dichotomous (present or absent), categorical (none, mild, moderate, severe) or interval (analogue or Likert) scales. Analogous to NNTs, the number needed to harm (NNH) may be used to describe the incidence of adverse effects.

Most efficacy trials will have inadequate power to detect rare adverse effects and therefore they are also absent from systematic reviews. Large clinical trials specifically designed to detect adverse effects are required (eg the Vioxx Gastrointestinal Outcomes Research [VIGOR] study

investigated gastrointestinal toxicity of NSAIDs) (Bombardier 2000 **Level II**, n=8,076, JS 5). Case reports and post-marketing epidemiological research and surveillance (eg the Australian Adverse Drug Reactions Advisory Committee) remain important for detection of delayed effects occurring after the initial trial period. Results from comprehensive large prospective audits and database reviews have provided a sufficiently reliable denominator for incidence and risk factor evaluation in rare but serious adverse effects in acute pain management (Wijeysundera 2008b **Level IV**, n=259,037; Cameron 2007 **Level IV**, n=8,210; Wijeysundera 2008a **NR**).

Besides the adverse effects attributed to acute pain management interventions, another area of interest is whether the adverse effects of trauma and surgery might be prevented by effective acute pain management. Outcomes such as mortality, morbidity due to derangements of the cardiovascular, respiratory, gastrointestinal and coagulation systems and progression to chronic pain have also been reported (see Chapter 1).

KEY MESSAGE

1. Assessment of pain relief (with total pain relief [TOTPAR]) may be more sensitive to treatment effects than assessment of intensity (with summed pain intensity difference [SPID]) (**N**) (**Level I** [PRISMA]).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Multiple outcome measures are required to adequately capture the complexity of the pain experience and how it may be modified by pain management interventions (**U**).

3.1 | Education

3.1.1 | Patients

Patients and carers who learn about assessment of pain, the risks and adverse effects of treatment, and who are informed that they should communicate both the effectiveness of treatment and any adverse effects, will have greater control over the quality of their pain relief. Information on treatment options, goals, likely benefits and probability of success should be available; this advice is found in most published recommendations and guidelines. Despite this, many patients still feel uninformed about pain, particularly in the perioperative period (Macintyre 2015 **NR**; Counsell 2008 **NR**). A national survey of patients who were undergoing total hip arthroplasty (THA) revealed that 70% did not believe they had been given adequate information about their procedure (including pain relief) and those who had higher levels of education perceived a larger deficit (Johansson Stark 2014 **Level IV**, n=320). A survey of health professionals acknowledged that perioperative pain management knowledge and other aspects of colonic surgery were deficient in patients undergoing the procedure (Sjostedt 2011 **Level IV**, n=49 [health care professionals]).

3.1.1.1 | General principles

A systematic review of systematic reviews (using the AMSTAR 1 tool) pertaining to methods of patient education, in general, concludes that teaching strategies that increase patient knowledge decrease anxiety and improved patient satisfaction (Friedman 2011 **Level IV SR**, 23 systematic reviews & meta-analyses, n unspecified). This comprised those using computer technology, audio and videotapes, written materials and demonstrations. While only one systematic review addressed pain management, the more general results are relevant to this topic. Educational strategies were better when combined, structured, culturally appropriate and patient-specific, rather than generic or *ad hoc*. Verbal teaching and discussions were found to be the least effective strategies. Web-based teaching improved patient knowledge, anxiety, and satisfaction, as did audiotapes, videotapes, written materials and lectures, all of which were more effective than verbal teaching and discussions. Demonstrations had the highest effect of any of the teaching strategies evaluated. Multiple teaching strategies are better than single ones, with one systematic review finding that 67% of patients who received patient education using several different strategies had better outcomes than those who received routine care.

Patient education regarding the procedure or recovery provided a small improvement in postoperative pain (SMD -0.21; 95%CI -0.02 to -0.39) (12 RCTs, n=1,242), pre-operative anxiety (SMD -0.27; 95%CI -0.10 to -0.44) (12 RCTs, n=1,260) and postoperative anxiety (SMD -0.26; 95%CI -0.08 to -0.43) (11 RCTs, n=921), but had no impact on analgesic use (SMD -0.06; 95%CI 0.13 to -0.24) (10 RCTs, n=860) (Szeverenyi 2018 **Level I** [PRISMA], 62 RCTs, n=4,908). Pain psychoeducation undertaken before surgery (pre-emptive) or throughout the perioperative period (preventive) is an underutilised component of multimodal analgesia with data showing reduced pain intensity, analgesic use, LOS, return to ED, patient anxiety and possibly chronic postsurgical pain (Horn 2020 **Level IV SR**, 33 studies, n unspecified).

There is evidence that written information is better than verbal education. Written information resulted in more satisfaction, lower pain scores and lower analgesic use after gynaecological cancer surgery (Angioli 2014 **Level II**, n=190, JS 2). Knowledge was lower in those given non-standardised verbal information vs those given written information, including information regarding pain management, at the time of preoperative anaesthetic review

(Binhas 2008 **Level III-3**, n=180). Patients receiving education favoured the combination of verbal plus written information over verbal information alone, as it allowed them to refresh their memory (Andersson 2015 **Level III-1**, n=18). A study of emergency department patients found that the provision of patient information leaflets improved doctor-patient communication and patient satisfaction levels and reduced rates of reattendance for the same condition, as well as the number of drug prescriptions by doctors (Sustersic 2019 **Level III-2**, n=324). This aligns with the findings of a previous systematic review of systematic reviews which determined that patient information leaflets improve patient knowledge, satisfaction and adherence to treatment recommendations (Sustersic 2017 **Level IV SR**, 24 SRs, n unspecified).

A systematic review of studies of postoperative education (conducted between 1986 and 2007) which aimed at improvement in self-knowledge and symptom experience (including pain) evaluated the best type and amount of postoperative education (Fredericks 2010 **Level III-3 SR**, 58 studies, n=5,271). All types of surgery were included with 46% assessing cardiac surgery, 26% general surgery, 4% abdominal/ colorectal surgery and 5% hip and knee surgery. Individualised education with the patient having input into their educational requirements, use of combined media for delivery, provision of one-on-one education and multiple sessions were associated with improvement in educational and/or health outcomes. Individuals <50 y and those with higher educational level showed the highest benefit.

3.1.1.2 | Effects in specific postoperative settings

PCA use

Structured vs brief patient education prior to PCA use resulted in improved patient knowledge of PCA (Yankova 2008 **Level III-1 SR**, 5 RCTs & 1 study, n=592). No studies demonstrated that structured education about PCA improved postoperative pain scores.

Total joint arthroplasty

Three overlapping reviews draw similar conclusions as to the limited effect of preoperative patient education in addition to standard care on pre and postoperative outcomes after total hip and knee arthroplasty (THA/TKA) (McDonald 2014 **Level I** [Cochrane], 18 RCTs, n=1,463; Aydin 2015 **Level I** [PRISMA], 12 RCTS, n=1,567; Louw 2013 **Level III-1 SR**, 12 RCTs & 1 study, n=1,021) (10 & 8 RCTs overlap). The included RCTs are heterogeneous in terms of the patient population and teaching methods applied. There is some reduction in preoperative anxiety for THR (MD -5.10/60; 95%CI -7.17 to -3.03) (4 RCTs, n=333) and LOS for TKR (MD -1.86 d; 95% CI -3.40 to -0.32) (2 RCTs, n=183); but little or no evidence for any other outcomes including postoperative anxiety, mobility, pain, function or postoperative complications.

Preoperative education does not improve postoperative pain scores after either THA (up to 3 mth after surgery) or TKA (up to 12 mth after surgery) (McDonald 2014 **Level I** [Cochrane], 18 RCTs, n=1,463). However, education has a low risk of adverse effects, and may be beneficial for certain patients with depression, anxiety or unrealistic expectations about their surgery.

Interviews with focus groups of patients following THA and TKA identified patient requests for increased education on pain management in the postoperative period (Kennedy 2017 **Level IV**, n=32). Patients reported that they would have preferred more information regarding expected levels of postoperative pain, the purpose, administration and expected side effects of analgesic medication, and specific weaning instructions. Among the patients interviewed, there was a wide range of preference for content, mode of delivery (web-based or traditional methods), and timing of education. It is acknowledged in the literature that a more personalised education program that allows patients to ask questions may translate to improved outcomes following preoperative education (Aydin 2015 **Level I** [PRISMA], 12 RCTs, n=1,567). However, a randomised controlled trial that involved personalised preoperative information sessions prior

to TKA did not demonstrate any difference in pain at any time point vs a group receiving standard care (Wilson 2016 **Level II**, n=143, JS 4). The authors suggest that this may reflect a requirement for increased education for healthcare providers as well as patients in order to achieve significant benefits in postoperative analgesia. Online resources available for patients to read about pain control after TKA are generally of limited utility, with more than 90% of websites containing information directed at patients written in language that exceeds average reading levels (Schairer 2017 **NR**). This has the potential to limit patient understanding of postoperative pain management and highlights an opportunity for orthopaedic, anaesthetist and pain medicine specialists to develop and encourage access to appropriate patient-focused online resources.

Cardiac surgery

Preoperative education reduces anxiety (6 RCTs, n=829) in patients undergoing mixed types of cardiac surgery, but there was limited evidence for any effect on pain (4 RCTs, n=704) (Ramesh 2017 **Level I** [PRISMA], 14 RCTs, n=2,071). This is consistent with a preceding systematic review which found no effect of preoperative education on pain levels or other outcome measures in patients after coronary artery bypass graft (CABG) surgery (Guo 2015 **Level I**, 6 RCTs, n=1,406 [2 RCTs pain, n=762]) (2 RCTs overlap).

Spinal surgery

Patients receiving neuroscience education (including a conversation with a physical therapist for 30 min plus a neuroscience booklet) prior to lumbar spinal surgery for radicular pain had the same pain levels and function 12 mth following surgery vs controls who received routine care (Louw 2014 **Level II**, n=67, JS 3). However, those in the experimental group exhibited 45% less healthcare expenditure in the 12 mth following surgery and viewed their surgical experience more positively. At 3 y follow-up, this reduction in health care costs was maintained; the group that received preoperative neuroscience education spent 37% less on medical expenses (Louw 2016 **Level III-2**, n=50). The authors postulated this could be a result of the educational emphasis on neurobiology and neurophysiology (central and peripheral sensitisation, facilitation and inhibition) as opposed to the pathoanatomical explanation previously utilised for education in patients undergoing lumbar spinal surgery.

A preoperative educational intervention (provision of a detailed information booklet and 30 to 40 min guided explanation by a nurse) vs control in spinal surgery lowered preoperative anxiety and postoperative pain scores (6.1/10 to 5.3/10) (Lee 2018 **Level II**, n=86, JS 3) (see also Section 7.1.1).

Other types of surgery

The provision of a detailed information sheet to parents after tonsillectomy in children provided postoperative benefit (Bailey 2015 **Level II**, n=60, JS 5). The information sheet contained specific instructions regarding the dose and timing of oxycodone and resulted in higher parental satisfaction and knowledge and some improvements in pain scores up to POD 7 vs standard verbal instructions.

After cosmetic day-surgery procedures, preoperative education reduced postoperative opioid requirements and pain intensity and duration (Sugai 2013 **Level II**, n=135, JS 2). Preoperative written and verbal education (two sessions by the same surgeon) on the adverse and negative effects of opioids resulted in 90% of the treatment group declining an opioid prescription vs 100% filling their opioid prescription in the control group.

Patients undergoing modified radical mastectomy, who had received a specific 20 min education about their analgesia management and medications, reported less pain and mobilised earlier than those who had not received the education (Sayin 2012 **Level III-1**, n=84).

3.1.1.3 | Effects in other acute pain settings

The effect of patient education has also been studied in patients with acute non-surgical pain.

Education programs, depending on their approach, may not be effective in the prevention and treatment of neck pain or low back pain in a widely heterogeneous patient and community groups (including children and at-risk workers) (Ainpradub 2016 **Level I**, 15 RCTS, n=10,488); these findings were cautioned against in a letter (Hurley 2016), because they were based excessively on a "biomedical education" approach which emphasises "*protecting the injured back*". This type of education has now been supplanted by the effective "biopsychosocial education" approach, which in contrast, emphasises the robustness of the back, and is in agreement with pain physiology. Another systematic review shows a beneficial outcome from patient education in the management of acute lumbar back pain when a "biopsychosocial/neuroscience" education-based approach is used (Traeger 2015 **Level I** [PRISMA], 14 RCTs, n=4,872). In this review, the outcomes were "*reassurance*" (which was a composite of anxiety, fear, worry, distress) and healthcare utilisation (number of primary care visits for LBP over 12 mth). The effect size for a benefit on reassurance at 4 mth was SMD -0.21 (95%CI -0.36 to -0.07), and the effect on reduction in healthcare utilisation was SMD -0.14 (95%CI -0.28 to 0.00).

Regarding acute back pain, there is moderate to high quality evidence that patient education provided by primary care practitioners can reassure patients for up to 12 mth, and lead to reductions in low back pain related healthcare utilisation, with a NNT of 17 to prevent one subsequent primary care visit (Traeger 2015 **Level I** [PRISMA], 14 RCTs, n=4,872). Patient reassurance is heightened with education provided by a physician rather than by other health professionals. Conversely, a subsequent RCT found that the addition of two sessions (1 h each) of patient education (focusing on biopsychosocial contributors to pain as well as self-management techniques) to standard practice did not improve pain intensity or disability vs a placebo educational intervention (Traeger 2019 **Level II**, n=202, JS 4).

An earlier systematic review of pain education strategies for neck pain was unable to find good evidence for the benefit of patient education, apart from one RCT (n=348) showing that an educational video of advice about being active was more beneficial in the medium term (Gross 2012 **Level I** [Cochrane], 15 RCTs, n=5,305) (3 RCTs overlap with Ainpradub 2016). After acute whiplash injury specifically, short educational interventions reduce pain and disability and enhance recovery and mobility (Meeus 2012 **Level I** [PRISMA], 10 RCTs, n=1,594) (2 RCTs overlap). Educational interventions for patients with whiplash (neurophysiology content) have demonstrated improvements in both pain behaviours and pain threshold (Rebbeck 2017 **NR**). It is also recommended that patients receive advice regarding the course of recovery and education about coping strategies and unhelpful beliefs.

Antenatal education regarding epidural analgesia led to more primigravid women indicating that they would request epidural analgesia for pain relief in labour (Alakeely 2018 **Level III-3**, n=81). Antenatal teaching about postnatal nipple pain and trauma resulted in reduced nipple pain and improved breastfeeding (Duffy 1997 **Level II**, n=70, JS 3).

An emergency department nurse-delivered opioid education intervention (verbal and written communication strategies) increased patient understanding of appropriate use of discharge opioids (Waszak 2018 **Level III-3**). However, this relied on nurses' ability to take extra steps in their usual discharge routine, including printing information sheets and conducting verbal 'teach-back' sessions.

3.1.1.4 | Web-based education for acute pain management

The internet and mobile devices are being increasingly used for pain education. There are few published studies that have evaluated these types of interventions for patients with acute pain. A systematic review of web-based pain education included only two RCTs that evaluated educational websites with information on acute postoperative pain (Bender 2011 **Level I**, 17 RCTs, n=2,503): one aimed to prepare adolescents for tonsillectomy and demonstrated improvements in satisfaction and knowledge, but no difference in pain scores or anxiety (O'Conner-Von 2008 **Level II**, n=69, JS 3); the other prepared adults for postoperative self-care after outpatient surgical procedures and found reductions in postoperative pain intensity the night and day afterwards (Goldsmith 1999 **Level II**, n=195 [only 80 at follow-up], JS 2). An innovative web technology used an assessment process to individualise the content of education and use persuasive educational techniques to effect changes in response to pain after cardiac surgery (Martorella 2012 **Level II**, n=60, JS 3). The 30 min web-based intervention used a virtual nurse to guide the patient, followed by two face-to-face 5-min booster sessions. In the experimental group, patients did not experience less intense pain, but they reported significantly less pain interference when breathing/coughing and used more analgesia. A web-based intervention program providing daily postural advice and exercise instructions with daily email reminders and personalised log over 9 mth to office workers with sub-acute low-back pain (of 6 wk duration) was effective in improving quality of life, behaviour change, function and pain vs standard care (del Pozo-Cruz 2013 **Level II**, n=100, JS 2).

A systematic review found no additional benefit for tailored vs standardised web-based patient education for patients with chronic pain (Martorella 2017 **Level I** [PRISMA], 16 RCTs [15 chronic], n=4,304).

The readability of web-based educational materials regarding epidural analgesia was well above the recommended reading level for patient education, which may limit the ability of patients to make informed choices (Patel 2015 **Level IV**, n=101 [educational materials on 128 websites in English and Spanish]). An assessment of online patient education material about regional anaesthesia produced by USA teaching hospitals found the mean (SD) Flesch-Kincaid Grade Level for patient education material was high at hospitals offering and not offering regional fellowship teaching programs: 13.8 (2.9) vs 10.8 (2.0) ie well above the recommended sixth-grade level (Kumar 2017 **Level III-3**, n=32 [websites]). Similarly, a review of patient education material about safe opioid use after surgery found the online information from the websites of selected North American academic medical centres to have the reading grade level 7.84 (SD 1.98) (Kumar 2019 **Level III-3**, n=38 [websites]).

3.1.2 | Staff

Appropriate education of medical and nursing staff is essential if more sophisticated forms of analgesia (eg PCA or epidural analgesia) are to be managed safely and effectively and if better results are to be gained from conventional methods of pain relief (Macintyre 2015 **NR**). Medical and health professional staff education may take several forms; the evidence for any benefit for the best educational technique is varied and inconsistent. Education may also include organisational approaches, the provision of guidelines and accompanying changes to practice to enable good outcomes.

3.1.2.1 | Nursing staff

Improvements in nursing knowledge and ability to manage epidural analgesia followed the reintroduction of an epidural-education program using an audit/guideline/problem-based teaching approach, accompanied by practical assessments (Richardson 2001 **Level III-3**). A more

recent simulation-based educational workshop (4 h) relating to epidural assessment improved knowledge and confidence of participating nursing staff and increased the number of correct procedures performed in a post-workshop assessment (Sawhney 2018 **Level III-3**). However, translation to practice changes in the clinical environment was not assessed, and educational workshops of this type require significant time and monetary investments. Pain documentation in surgical wards (Ravaud 2004 **Level III-1**, n=2,278; Karlsten 2005 **Level III-2**) and intensive care units (ICUs) (Erdek 2004 **Level III-3**; Arbour 2003 **Level IV**) was also improved by education programs. A quality-improvement system, which included education and guidelines as well as systems to improve practice, resulted in significant improvements in postoperative pain, nausea, vomiting and fatigue (Usichenko 2013 **Level III-3**, n=520). Implementation of a quality-improvement program led to improvements in nurses' knowledge and assessment of pain using pain-rating scales; however, while the number of patients assessed increased, there was no improvement in pain relief (Hansson 2006 **Level III-2**).

There are possible reasons why education programs may not always be successful in improving nursing staff knowledge or attitudes (Dahlman 1999 **Level III-3**) or pain relief (Knoblauch 1999 **Level IV**). In rural and remote settings, distance and professional isolation could affect the ability of healthcare staff to receive up-to-date education about pain relief. However, similarities between urban and rural nurses' knowledge and knowledge deficits relating to acute pain management have been reported (Kubecka 1996 **Level IV**, n=123 [nurses]) and a tailored education program in a rural hospital improved the management of acute pain (Jones 1999 **Level III-3**, n=126). An education program delivered to nurses in rural and remote locations and focusing on acute, chronic and cancer pain improved understanding of pain management (Linkewich 2007 **Level III-2**). Early attempts at using online education for nurses to improve pain management were not widely accessed. A proposed model involving e-learning and problem-based approaches have had some initial success (Keyte 2011 **NR**).

A range of didactic and interactive teaching methods have been applied in nursing pain management education (Drake 2017 **Level IV SR** [PRISMA], 12 studies, n≈726 [staff] & n≈8,124 [patients]). Overall, nurses showed an improvement in pain documentation after participating in a pain management education program. However, there was no assessment of the nurses' associated behavioural change, and failure to account for the challenges of daily nursing practice, such as the requirement to frequently shift attention, which may interfere with assessment and ability to empathise with patients in pain). The provision of information and skills has limited ability to improve patient outcomes if these practical barriers to pain management are not addressed.

3.1.2.2 | Physiotherapists

Physiotherapists have recognised the need for more education about acute and subacute pain incorporating a biopsychosocial approach to prevent long-term disability and pain. However, an 8 d university course about how to identify and address psychosocial risk factors attended by practicing musculoskeletal physiotherapists led to no improvement in their patients being treated for musculoskeletal problems (Overmeer 2011 **Level II**, n=42, JS 2). The authors suggest that this type of teaching may be more effective if incorporated at an earlier stage of learning or by other methods if an impact on practice is to be made.

3.1.2.3 | Medical staff

Education of junior emergency department medical staff improved patient pain relief (Jones 1999 **Level III-3**, n=126). Additionally, the implementation of an education program with guidelines for pain management improved analgesia and patient satisfaction (Decosterd 2007 **Level III-2**, n=441).

A number of studies have shown the benefits of education and/or guidelines on improved prescribing patterns both in general terms (Ury 2002 **Level III-3**, n=1,006; Humphries 1997 **Level III-3**) and specifically for NSAIDs (Ray 2001 **Level II**, n=209, JS 2; Figueiras 2001 **Level III-2**, 495 [doctors in north-western Spain]; May 1999 **Level III-3**, n=210 [doctors in South Australia]), paracetamol (acetaminophen) (Ripouteau 2000 **Level III-3**, n=35 [French anaesthetists and nurses]) and pethidine (meperidine) (Gordon 2000 **Level III-3**).

A pilot program facilitated within Stanford University's Clinical Pain Medicine Fellowship program has implemented simulation as a method of medical education in opioid prescription (Heirich 2019 **Level III-3**, n=27).

3.1.2.4 | Interprofessional

Interprofessional education programs involving medical and nursing staff may improve collaboration and communication between health care team members and patients, and therefore encourage active self-management techniques and limit the implementation of passive pain management strategies (Hogans 2018 **NR**). An educational program (2 h) consisting of an interactive e-learning module and simulation session to both nursing and medical staff improved knowledge, but did not change analgesic administration or pain reduction for patients during an emergency department admission (Friesgaard 2017 **Level III-3**, n=2,140). The authors suggest that achieving behavioural change in healthcare professionals is complex, requiring repeated education, changes in workplace attitudes towards pain management, modification of daily practice environments and continuous support and follow-up.

Junior medical staff education over 3 y in an Australian tertiary hospital reduced inappropriate oxycodone IR prescriptions from 28% to 10% (Stevens 2019 **Level III-2**). The education package included junior medical and anaesthetic staff group and individual education (with feedback from audit data on individual prescribing), implementation of pharmacist-monitored prescription guidelines, an educational patient pamphlet and education sessions for surgical nursing staff regarding how to discuss opioid weaning and disposal.

3.1.2.5 | Web-based

There is growth in web-based delivery of education programs for health professionals. Online educational resources improve knowledge and skills, but not confidence and competence, (Liossi 2018 **Level IV SR** [PRISMA], 13 RCTs & 19 studies, n unspecified). Notably, there was significant heterogeneity among studies and relevant health outcomes for patients were not assessed. A survey of clinicians who completed an interactive online learning module regarding opioid prescription determined that clinician knowledge, the likelihood of adherence to prescription guidelines, and perceived competence in opioid prescription improved following participation (Langford 2020 **Level III-3**, n=167).

3.1.2.6 | Guidelines

When combined with education, the introduction of medical and nursing guidelines may contribute to improvements in pain management and prescribing practices (Gould 1992 **Level III-2**, n=2,035; Harmer 1998 **Level III-3**, n=2,738). Several initiatives have been described which employ guidelines with the aim of safe opioid prescription:

- A targeted medical, nursing and patient education initiative significantly reduced the median quantity of opioid analgesics provided at discharge for trauma patients (Oyler 2018 **Level III-3**, n=913);

- An emergency department opioid prescribing guideline reduced the number of discharge opioid prescriptions for dental, neck, back or chronic pain presentations from 53% (6 to 12 mth prior to introduction) to 34% (12 to 18 mth following introduction) (del Portal 2016 **Level III-3**, n=13,187);
- An Australian tertiary hospital introduced discharge analgesia prescribing guidelines which initially improved discharge prescribing practices, but diminished over time (Stewart 2019 **Level III-3**, n=170 [discharge prescriptions]). Maintaining education of junior medical staff can be a resource and time intensive proposition and is often maintained in an informal manner by pharmacists and other healthcare team members.

Advances in pain education require the engagement of healthcare professionals, patients, stakeholders, and ultimately a better understanding of pain education research (Hogans 2018 **NR**). Pain education research continues to present multiple challenges in terms of definition of content, ethical and practical study design, and consideration of appropriate outcome measures.

The importance of pain medicine education at an undergraduate medical level has also been recognised. A cross-sectional study of medical school curricula across Europe (Advancing the Provision of Pain Education and Learning [APPEAL] study) demonstrated that current undergraduate medical pain education is not consistent with that which would be expected given the current prevalence of pain conditions and their associated public health burden (Briggs 2015 **Level IV**, n=242 [curricula of medical schools]). Of 242 medical schools, only 31% offered a dedicated pain module and only 18% of these were compulsory, while 7% lacked any pain education. In response to the prescription opioid epidemic, American medical schools have implemented curriculum changes to include pain management and opioid prescribing (Barth 2017 **NR**). Furthermore, a systematic review of all articles that examined the content of pain education in medical school curricula found that the number of teaching hours was limited, and most had no mandatory formal pain medicine program (Shipton 2018 **Level IV SR**, 14 studies, n=383 [medical schools]); this did not reflect the healthcare needs for pain management in the population. Anaesthetists and acute pain services are central to the education of junior medical staff and development of hospital and state-wide prescription guidelines, and thus it is important that anaesthetists themselves receive appropriate exposure to acute pain medicine during their training (Macintyre 2014 **NR**).

KEY MESSAGES

1. There is no good evidence in favour of general education for acute neck pain having significant effects on any relevant outcomes (**U**) (**Level I** [Cochrane Review]).
2. Short educational interventions in acute whiplash injury reduce pain and disability and enhance recovery and mobility (**U**) (**Level I** [PRISMA])
3. There is limited evidence that preoperative education may lead to small improvements in postoperative outcomes such as pain, preoperative and postoperative anxiety, but not in analgesic requirements (**Q**) (**Level I** [PRISMA]).
4. General “biomedical” education in patients with acute back pain does not reduce pain or improve other outcomes (**S**) (**Level I**); however, education using a “biopsychosocial/ neuroscience” approach reduces a composite of anxiety, fear, worry, distress and healthcare utilisation (**N**) (**Level I** [PRISMA]).

5. Targeted reassurance in acute back pain by physicians in primary care can result in improved changes in psychological factors such as fear, worry, anxiety, catastrophisation and healthcare utilisation (**U**) (**Level I** [PRISMA].
6. Preoperative education improves patient or carer knowledge of pain and encourages a more positive attitude towards pain relief (**U**) (**Level II**).
7. Specific pain neuroscience education in specific surgical settings may result in less healthcare utilisation (**U**) (**Level II**).
8. Written information given to patients is better than verbal information given at the time of the interview (**S**) (**Level II**).
9. Educational interventions in cancer pain patients improve knowledge, attitudes and pain control (**U**) (**Level III-1 SR**).
10. While evidence for the benefit of patient education in terms of better pain relief is inconsistent, structured preoperative education may be better than routine information (**U**) (**Level III-2**).
11. Staff education and the use of guidelines improve pain assessment, pain relief and prescribing practices (**S**) (**Level III-3**).
12. Pain psychoeducation undertaken before surgery (pre-emptive) or throughout the perioperative period (preventive) is an underutilised component of multimodal analgesia which may reduce pain intensity, analgesic use, length of stay, return to the emergency department, patient anxiety and possibly chronic postsurgical pain (**N**) (**Level IV SR**).
13. Pain score documentation improves with various forms of nursing education, but the impact of this behaviour change has not been adequately assessed (**N**) (**Level IV SR**).
14. Pain medicine education in medical school curricula is restricted in scope and content (**N**) (**Level IV SR**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Successful management of acute pain requires close liaison between all personnel involved in the care of the patient (**U**).

☑ More effective acute pain management will result from appropriate education and organisational structures for the delivery of pain relief rather than the analgesic techniques themselves (**U**).

3.2 | Organisational requirements

It is recognised that patients should be able to access best-practice care, including appropriate assessment of their pain and effective pain management strategies (ASA 2012 **GL**; ANZCA 2010 **GL**). However, effective acute pain management will, to a large extent, depend not only on the medicines and techniques available, but also on the systems involved in their delivery (Macintyre 2015 **NR**). Even simple methods of pain relief can be more effective if proper attention is given to education (see Section 3.1 before), prescribing, administration, documentation, monitoring of patients and the provision of appropriate policies, protocols and guidelines (Gould 1992 **Level III-3**, n=2,035). The incorporation of pain measurement into clinical assessment for all patients, not only those under the care of an Acute Pain Service (APS), will aid pain management for all the patients throughout an institution (Gordon 2008 **NR**). Standardised clinical observation charts which include pain, sedation and function scores with other vital signs are an important step in ensuring safe provision of effective analgesia (Macintyre 2015 **NR**). In many institutions, an APS will assume responsibility for managing complex patients and more advanced methods of pain relief such as PCA, epidural analgesia and perineural infusions.

3.2.1 | General requirements

Guidelines to enhance patient outcomes and standardise analgesic techniques (eg selection of medicines and their concentrations, dose and dose intervals), monitoring requirements, choice of equipment, and responses to inadequate or excessive analgesic doses or other complications lead to consistency of practice. This can potentially improve patient safety and analgesic efficacy, regardless of the technique used (Macintyre 2015 **NR**; Counsell 2008 **NR**). These guidelines should be evidence-based wherever possible.

Marked improvements in conventional methods of pain relief have followed the introduction of guidelines for parenteral opioid administration (Humphries 1997 **Level III-3**, n=242; Gould 1992 **Level III-3**, n=2,035). However, it is the implementation of guidelines, not their development that remains the greatest obstacle to their use. Compliance with available guidelines is highly variable and may be better in larger and university-affiliated hospitals (Nasir 2011 **Level IV**, n=301 [USA hospitals]; Carr 1998 **Level IV**, n=400 [USA hospitals]). Resource availability, particularly staff with pain management expertise, and the existence of formal quality-assurance programs to monitor pain management are positive predictors of compliance with guidelines (Jiang 2001 **Level IV**, n=220 [USA hospitals]).

Different types of surgery require different types of analgesic regimens. Common and minor surgical procedures often result in high pain scores, which are frequently undertreated (eg laparoscopic appendicectomy, cholecystectomy, and haemorrhoidectomy) (Gerbershagen 2013 **Level IV**, n=70,764). The adoption of procedure-specific methods and the use of analgesic combinations may help to optimise analgesia and reduce adverse effects (Joshi 2013 **NR**) (see Section 8.1.3). A hospital-wide approach can be incorporated into postoperative enhanced-recovery programs (White 2010 **NR**) (see Section 3.2.3 below).

Professional bodies in a number of countries have issued guidelines for the management of acute pain (RCoA 2020 **GL**; Agency for Clinical Innovation NSW 2016 **GL**; Faculty of Pain Medicine RCoA 2015 **GL**; ANZCA 2013 **GL**; ASA 2012 **GL**).

While there is widespread agreement about the value of clinical guidelines, they do have limitations. Some of these include reliance on the population-wide aggregation of patient outcomes, which may not be optimal on an individual patient level. Individual patient

variability arises from complex interactions between genetic and environmental exposures over the life of the patient (Fillingim 2017 **NR**). A method that can incorporate standardised care but allow for individual patient variation is the SCAMP approach – Standardised Clinical Assessment and Management Plans (Beverly 2017 **NR**). This process is a clinician-engaged approach that promotes standardisation but accommodates patient preferences, includes clinician experience and incorporates recent medical knowledge. Benefits include reduced variability in medical care (Farias 2013 **NR**).

The success of an APS and patient treatment depends not only on good clinical care but also on a positive organisational culture(Powell 2009 **NR**; Bate 2008 **NR**). This should follow the key principles of effective change management. A series of semi-structured interviews of healthcare professionals identified key areas that need to be addressed for well-organised care. These include structural issues, political issues, cultural change, educational challenges, leadership and motivation, and technological challenges.

3.2.2 | Acute pain services

There is a very wide diversity of APS structures, with no consensus as to the best model and no agreed definition of what might constitute such a service (Counsell 2008 **NR**). Some are "low-cost" nurse-based (Shapiro 2004 **Level IV**, n=4,617; Rawal 2005 **NR**), others are anaesthetist-led but rely primarily on APS nurses as there may not be daily clinical participation by an anaesthetist (Nagi 2004 **NR**; Harmer 2001 **NR**). In contrast, others are comprehensive and multidisciplinary services with APS nursing staff, sometimes pharmacists or other staff (eg clinical psychologists) (Katz 2015 **NR**) and daily clinical input from and 24 h cover by anaesthetists (Macintyre 1990 **Level IV**, n=1,053; Ready 1988 **Level IV**, n=820; Schug 1993a **NR**). The development of specific paediatric pain services has also been described (Kost-Byerly 2012 **NR**) and is an emerging field (Finley 2014 **NR**).

Larger hospitals and those with university affiliations are more likely to have a formal APS and use protocols (Nasir 2011 **Level IV**, n=301 [USA hospitals]). When advanced modalities such as epidural analgesia and continuous peripheral nerve block (CPNB) are used, the APS is most commonly anaesthetist-led. An economic evaluation of a physician-led APS has shown it to be cost-effective even for patients having IV PCA after intermediate grade surgical procedures (Lee 2010 **Level II**, n=423, JS 2).

The degree of medical input varies enormously. A UK survey reported that while 90% of hospitals reported having an APS, dedicated medical staff sessions did not exist in 37%, were limited to one or two per wk in 40% and in only 4% were there five or more sessions (Nagi 2004 **NR**). In training hospitals in Australia, 91% of hospitals accredited for anaesthetic training had an APS run from the department of anaesthesia with daily input from medical staff. Consultant anaesthetist sessions (one session is 0.5 d) varied from zero in 27%, just one or two a wk in a further 22%, four to six per wk in 22% and ten per wk in 15% (Roberts 2008 **Level IV**, n=67 [AUS and NZ hospitals]). A UK survey of 141 acute pain services found variation in the structure, function and staffing of the APSs between the responding hospitals (Rockett 2017 **Level IV**, n=209 [UK hospitals]). The mean number of consultant hours per wk was only 5.5 h. 35% of the APSs also had other roles in addition to acute pain management. Only half of the teams (49%) had members that also worked in an integrated multidisciplinary pain service. A Dutch survey showed again that 90% of hospitals have an APS of variable organisational structure; important tasks of the APS were regular patient rounds and checking complex pain techniques (100%), supporting quality improvement of pain management (87%), pain education (100%) and pain research (21%) (van Boekel 2015 **Level IV**, n=96 [Dutch hospitals]). However, a survey repeated in Denmark from 2000–2009 showed a surprising decline of APSs in parallel to the

increased usage of enhanced-recovery programs (Nielsen 2012 **Level IV**). In the USA, APSs were more common in university/academic hospitals (96%) than in Veterans' Affairs hospitals (69%), with the lowest rate in private hospitals (47%) (Nasir 2011 **Level IV**, n=301 [USA hospitals]). Formal written postoperative pain protocols were more common in hospitals with an APS but overall only 55% of hospitals had such protocols. In Germany, 81% of the hospitals surveyed stated that they had an APS; however, only 45% met quality criteria defined by the authors (Erlenwein 2014 **Level IV**, n=403 [German hospitals]). In contrast to the USA data above, 97% of the hospitals had written acute pain protocols for surgical patients, but only 51% on nonsurgical wards.

Some APSs supervise primarily "high-tech" forms of pain relief and/or complex patients, while others have input into all forms of acute pain management in an institution and will work towards optimising traditional methods of pain relief so that all patients in that institution benefit (Macintyre 2015 **NR**; Counsell 2008 **NR**; Breivik 2002 **NR**). Increasingly, APSs are also called on to deal with much more complex pain management issues (eg acute-on-chronic pain, acute pain after SCI or other major trauma, and resulting from a multitude of medical illnesses) and more complex patients (eg opioid-tolerant patients, older patients) (Counsell 2008 **NR**).

Individual publications assessing the benefits of an APS have reported that the presence of an APS reduced pain scores (Stadler 2004 **Level III-3**, n=1,975; Bardiau 2003 **Level III-3**, n=2,283; Salomaki 2000 **Level III-3**, n=400; Sartain 1999 **Level III-3**, n=605; Harmer 1998 **Level III-3**, n=2,783; Gould 1992 **Level III-3**, n=2,035; Miaskowski 1999 **Level IV**, n=5,837) and adverse effects (Sartain 1999 **Level III-3**, n=605; Stacey 1997 **Level III-3**, n=40; Miaskowski 1999 **Level IV**, n=5,837; Schug 1993a **Level IV**, n=3,016). A review of publications (primarily audits) looking at the effectiveness of APSs (77% were physician-based, 23% nurse-based) concluded that the implementation of an APS is associated with a significant improvement in postoperative pain and a possible reduction in postoperative neurological symptoms (PONS), but that it was not possible to determine which model was superior (Werner 2002 **Level IV SR**, 48 studies, n=84,097). The authors comment, however, that it is not possible to assess the contribution of factors such as an increased awareness of the importance of postoperative analgesia, the use of more effective analgesic regimens (eg epidural analgesia), the effects of APS visits and better strategies for antiemetic therapy. The benefits of an APS can be enhanced when its role is expanded beyond its traditional postoperative realm and into the entire patient journey – preoperative, intraoperative, postoperative and posthospital discharge (Zaccagnino 2017 **NR**).

Possible benefits of an APS are summarised in Table 3.1.

Given the heterogeneity of APS models and types of patients and pain treated, as well as variation in the quality of published studies, it is difficult to meaningfully analyse the benefits or otherwise of an APS. Although systematic reviews have been attempted (McDonnell 2003 **Level III-3 SR**, 15 studies, n unspecified; NICS 2003 **Level III-3 SR**, 32 studies, n unspecified) (4 Studies overlap), the poor quality of the studies looking at the effectiveness or otherwise of APSs and the many different types of APSs, means that a meta-analysis cannot be performed.

In addition, the above studies looked at outcome in terms of immediate pain and adverse effects in postoperative patients only. It is possible that an APS may benefit patients in other ways.

Combination of an APS with a physician-based critical-care outreach team, which systematically reviewed high-risk postoperative patients for 3 d after their return to a general ward, showed a significant improvement in postoperative outcome with a decrease in serious adverse effects from 23 to 16 events per 100 patients and 30 d mortality from 9 to 3% (Story 2006 **Level III-2**, n=590). Finally, members of an APS may also be more likely to recognise the early onset of neuropathic pain associated with surgery, trauma or medical disease and institute the appropriate treatment (Counsell 2008 **NR**).

Table 3.1 | Possible benefits of an acute pain service

Benefit	References
Better pain relief	Stadler 2004; Bardiau 2003; Werner 2002; Salomaki 2000; Sartain 1999; Gear 1999; Harmer 1998; Gould 1992
Lower incidence of adverse effects	Werner 2002; Sartain 1999; Miaskowski 1999; Stacey 1997; Schug 1993b
Lower postoperative morbidity/mortality	Story 2006
Management of analgesic techniques that may reduce the incidence of persistent pain after surgery	Gehling 2003; Senturk 2002; Obata 1999
Cost-effective patient care	Lee 2010
Reduced persistent pain and discharge opioid use after surgery	Tiippana 2016; Katz 2015

The role of an APS can be extended into the pre-admission (elective cases) and post-acute phase of recovery. This approach can bridge the gap between ward-based acute pain care and outpatient chronic pain management. Descriptions of this type of extended and proactive care suggests a reduction in the occurrence of persistent pain and excessive opioid use after hospital discharge, which may also be cost-effective (Tiippana 2016 **Level IV**, n=200; Katz 2015 **NR**) (see also 3.3 Economic Considerations).

3.2.2.1 | Safety

Unidimensional management of acute pain can lead to adverse outcomes including opioid-induced ventilatory impairment (OIVI) (Vila 2005 **Level III-3**; Macintyre 2011 **NR**). Structural changes in an APS can minimise such effects (Story 2006 **Level III-2**, n=590). Implementation of root-cause analysis for critical incidents improved the safety of patients looked after by an APS; this approach reduced the overall event rate (1.47% vs 2.35) with specific effects on the rate of respiratory depression (0.41% vs 0.71), severe hypotension (0.78% vs 1.34) and PCA pump programming errors (0.0% vs 0.08) (Paul 2014 **Level III-3**, n=35,384) (see also Sections 6.6 and 6.8).

Standardised written documentation of APS treatment can potentially improve the safety of patient care. An agreed and consistent format for prescribing, observation and documentation of care can reduce unnecessary clinical variation, which is beneficial (Agency for Clinical Innovation NSW 2016 **GL**). The use of an electronic medical record (EMR) can facilitate the function and safety of an institution's APS. Specifically, these benefits can include clear documentation, organisation of ward rounds, billing, analysis of patient safety and outcomes, and integration with research (Goldstein 2014 **NR**). It is important that the design of an EMR has features that facilitate usability, efficiency, safety and mobility (Telenti 2018 **NR**; Mandl 2012 **NR**; Grams 2009 **NR**). The integration of electronic smart-pumps directly into the EMR greatly increased the accuracy and completeness of recording PCA episode of care vs paper-based records (38% to 91) (Suess 2019 **Level III-3**, n=113).

KEY MESSAGES

1. Implementation of an acute pain service may improve pain relief and reduce the incidence of adverse effects (**U**) (**Level III-3**).
2. Even "simple" techniques of pain relief can be more effective if attention is given to education, documentation, patient assessment and provision of appropriate guidelines and policies (**U**) (**Level III-3**).
3. Implementation of root-cause analysis to follow up critical incidents improved the safety of patients under care of an acute pain service (**U**) (**Level III-3**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Successful management of acute pain requires close liaison between all personnel involved in the care of the patient (**U**).

☑ More effective acute pain management will result from appropriate education and organisational structures for the delivery of pain relief rather than the analgesic techniques themselves (**U**).

☑ Appropriate institutional support and engagement is important for the effective implementation of an acute pain service (**U**).

☑ Procedure-specific analgesic protocols can help optimise analgesia for the individual patient while reducing adverse effects (**U**).

☑ The adoption of individualised care pathways (eg SCAMPS) can improve patient outcomes and reduce clinical variation (**N**).

☑ The benefit of an acute pain service can be enhanced when acute pain management is integrated into the pre, intra and postoperative periods (**N**).

☑ The recruitment of patients 'at-risk' for persistent pain and/or excessive opioid use into a post-discharge treatment service for early review can improve outcomes (**N**).

☑ Appropriately designed, implemented and integrated Electronic Medical Records (EMR) can improve the standards of clinical care (**N**).

3.3 | Economic considerations in acute pain management

An economic evaluation of healthcare can be described as the "*comparative analysis of alternative courses of action in terms of their costs and consequences*" (Drummond 2008 **NR**). Health economics aims to maximise health benefits relative to the resources available. This approach is particularly crucial in a growing and ageing population, with fewer people in the workforce paying taxes, and a more substantial proportion with chronic conditions and aged care, requiring health services. An economic assessment of acute pain can be of the overall service provision (eg an APS), or a specific technique (eg PCA). Areas where acute pain management may affect the economics of healthcare include: patients, hospitals, and payers/insurers. These impacts may be direct or indirect, where the costs of delivering pain management may result in savings in other areas of patient treatment. Limited data indicate potential areas of cost savings arising from improved acute pain care. These include shorter ICU admissions, decreased cardiac and respiratory adverse events, decreased risk of postoperative infections, and potentially reduced risk of the development of chronic pain (Gray 2017 **NR**; Schug 2017 **NR**).

While the costs of healthcare are relatively easy to measure, the value of healthcare is harder to quantify (Goldman 2014 **NR**). Often, the benefits of healthcare are limited to those occurring within the healthcare system; however, there may be other significant benefits in society that should also be included eg return to full employment, long-term disability due to pain, or mental health related to ongoing pain (Drummond 2008 **NR**). The impact on a patients' family and carers in their workforce participation and their psychological well-being are further considerations (Schofield 2019 **Level IV**).

There are several types of economic assessment that are commonly used in the literature. These have important differences; there is a consensus agreement on their definitions (Husereau 2013 **GL**; Drummond 2005 **NR**) (see Table 3.2). The most commonly used is cost-effectiveness analysis, which examines the cost in dollars per additional life-year gained.

In the literature, these terms may be used interchangeably, without correct adherence to their definitions. No one assessment measure is superior to another, and health economists debate the merits of each. In addition, issues of social equity, needs, and priorities should also be part of the decision making process (Schlander 2009 **NR**; Phillips 2009 **NR**; McGregor 2003 **NR**).

In contrast to most commodities, healthcare is a "*credence good*" (Emons 1997 **NR**) ie patients or consumers/stakeholders find it difficult or impossible to determine the utility of a treatment prior to its consumption. They have to rely on the knowledge of healthcare experts when choosing a treatment. This situation is also referred to as "*asymmetry of knowledge*".

Patients value pain relief highly; a survey of two million USA inpatients found that "*how well their pain was controlled*" was the second most important factor in recommending a hospital (PressGaney 2009 **Level IV**). When healthcare funding occurs without regard to patient's values, then funding for formal acute pain services becomes limited (Sun 2010 **NR**).

A consistent risk factor for the development of chronic postsurgical pain (CPSP) is poorly controlled postoperative pain (see Section 1.4). CPSP is an economic burden on society. An economic report in 2019 found that the total cost of chronic pain in Australia was $73.2 billion, and that much of chronic pain originates as acute pain (Deloitte Access Economics 2019 **NR**). Chronic pain interferes with the return to employment, requires ongoing medical treatment with its inherent costs, and may require carers at an additional cost, or require informal care from a family member or friend, influencing their workforce participation (Schofield 2019 **IV**) .

Table 3.2 | Definitions of health economic assessment measures

Cost-effectiveness analysis	Consequences are measured in natural units, such as life years gained, disability days avoided, or cases detected
Cost-utility analysis	Consequences are measured in terms of preference-based measures of health, such as quality adjusted life years (QALY) or disability adjusted life years (DALY).
Cost-benefit analysis	Consequences are valued in monetary units
Cost-minimisation analysis	Consequences of compared interventions are equivalent (in terms of clinical efficacy and tolerability), and only relative costs are compared
Cost-outcome description	Costs measured in monetary value and health effects measured in natural units (eg intensive care unit days saved, patient satisfaction etc.)
Value of statistical life	A method to assign a monetary value to a person's life (or a proportion if a disability) using a willingness to pay approach. This is similar to a QALY. (Office of Best Practice Regulation 2014 **GL**)

Economic assessment of pain relief requires direct and indirect evaluation of both the costs and the benefits. Assessment of subjective experiences, such as a reduction in pain scores, can be assigned a monetary value using techniques such as 'willingness to pay', and 'human capital approaches' (Kumar 2006 **NR**). These monetary values can then be used in performing a cost-benefit analysis. Economic analysis needs to include the assessment of a treatment in comparison with the alternatives eg IV PCA vs prn opioid analgesia. Direct costs can include the cost of equipment, drugs and staff. Indirect costs can include the duration of hospital stay, use of ICU, development of persistent pain and treatment of adverse effects. Potential benefits include: reduction in pain intensity, minimisation of pain-related adverse effects, improved fast-track recovery and compliance with rehabilitation, as well as earlier return to work of both the patient and their informal carer (White 2007 **NR**).

3.3.1 | Economic evaluation of PCA

The direct and indirect costs of PCA for pain relief after three common types of surgery have been assessed (Palmer 2014 **Level III-3**, n=11,805,513). This evaluation used data from a large administrative healthcare database (Premier 2015 **Level IV**). Further cost estimates of adverse events were derived from the literature. The use of PCA after TKA, THA and open abdominal surgery was evaluated. The costs included PCA pump usage, setup costs, and costs of IV extension set, drug, fluid for IV co-infusion and the pump. The total of these costs (standardised to US$ in 2012) during the first 48 h after surgery, were US$204, US$196, and US$243 respectively. Additionally, cost estimates for particular adverse events in the first 48 h of PCA use were calculated. These costs were: phlebitis (US$2.18), healthcare worker needle stick injury (US$1.67), and IV PCA programming error (US$35.52). The assessment of costs for PCA programming errors did not include newer pumps that have software for the mitigation of programming errors (ie 'smart pumps'). The cost of other adverse events, such as respiratory depression or nausea and vomiting, were not included in this assessment.

The costs and rates of harmful and non-harmful errors due to the use of IV PCA were estimated from two large safety-reporting databases in the USA (Meissner 2009 **Level IV**): the datasets included medication errors (MEDMARX) and device errors (MAUDE). A cost-accounting methodology was used, which included direct, indirect and opportunity costs. These were estimated from published literature, expert consensus, physician billing-charges and staff labour-rates (standardised to US$ in 2006). The estimated average cost of a PCA adverse event in the medication error dataset was US$733, whereas the cost related to a pump error was US$552. If an error led to patient harm, then the cost was 120 to 250 times more costly than a non-harmful error. For medication incidents, the most expensive harm-causing error was due to poor communication (US$8,984 per incident). For pump-related errors, the two most expensive were operator error (US$5,756) and those of indeterminate cause (US$6,120). The estimated annual USA error rates per 10,000 patients treated with PCA were 407 for PCA medication errors, and 17 for PCA device errors (see also Section 6.6).

3.3.2 | Economic evaluation of Acute Pain Services

A narrative review (Gray 2017 **NR**) examined the economic aspects of an APS from within a USA healthcare perspective. Assessment included the areas of the patient, the hospital and the payer (insurer). Indirect benefits may include improved outcome over a range of postoperative measures. This may be relevant for a hospital within an 'activity-based funding' agreement. The use of continuous regional anaesthesia/analgesia techniques can be made more cost-effective by instigating a single regional block service that covers multiple operating rooms. This service model could reduce the cost of time delays associated with the initiation of regional anaesthesia. The treatment options used by a specialised acute pain service could ensure there is greater use of non-opioids, and mitigation of excess opioid prescribing with that resultant long-term health cost.

A systematic review of the economic evaluations of APSs has been performed (Lee 2007 **Level IV SR**, 9 studies, n=14,774). Five of the studies were of nurse-based, anaesthetist-supervised services. Out-of-pocket expenses and loss of productivity due to absence from work were not included. No study went beyond five d. Monetary values were standardised to $US in 2005. The cost of an anesthetist-led APS ranged from US$31.73 to US$100.37 per patient per d. The cost of a nurse-based/anaesthetist supervised APS ranged from US$3.70 to US$50.77 per patient per d. The cost-savings from a shorter ICU stay were US$9.90 per patient per d. The cost-savings from a shorter duration of hospital stay were US$11.40 per patient per d. Savings from reduced nursing time were also identified. Data were not available to compare the economics of a nurse-based/anaesthetist supervised APS with an anaesthetist-led APS. No studies were of high quality or included all costs and benefits associated with APS care.

An RCT for the cost-effectiveness of APS care (anaesthetist-led, nurse-based) compared APS patient care (IV PCA plus adjuvants) with conventional ward analgesia for patients having major surgery (Lee 2010 **Level II**, n=423, JS 2). Regional analgesic techniques were not included. Of patients in the APS group, 86% had one or more d of highly effective pain relief vs 75% in the conventional care group. Costs were higher in the APS group when compared with the conventional group by US$46/d. Cost-effectiveness was determined using a 'willingness-to-pay' methodology which assigns a monetary value to pain relief. This analysis showed that to be 95% certain of obtaining one d of highly-effective pain relief per patient, the benefit was valued at US$546.

The cost-utility analysis of a nurse-based APS has been performed (Stadler 2004 **Level III-3**, n=1,975). The interventions used in this APS were: implementation of guidelines, use of multimodal analgesia, optimum use of systemic opioids as well as NSAIDs and paracetamol,

along with information pamphlets to patients. In 1.5% of patients, PCA was used; patients receiving epidural analgesia were not included. The patient population was a large tertiary hospital that included all surgical subspecialties. Cost-utility was assessed using a measure of 'Postoperative Pain Days Averted (PPDA)', which is a health state scale conceptually similar to quality adjusted life years (QALY). The PPDA measure summarises treatment outcome in terms of time spent with lower pain scores. A value of "1" represents a state of "no pain", whereas a value of "0" represents "worst pain imaginable". For POD 1 to 3, PPDA values were 0.075 (1.8 h), 0.05 (1.2 h) and 0.0375 (0.9 h) respectively. The incremental cost of pain management by the APS vs no APS, was 19 Euro per patient per d. The effectiveness of the APS may have been different if more advanced methods of pain relief had been used. Measuring PPDA alone may have missed other benefits from improved pain relief (ie quality of life surveys such as SF-12).

3.3.3 | Economic benefit related to improved patient outcome and reduced chronic postsurgical pain.

While not intended as economic assessments, there are studies that have measured patient outcomes, other than pain, which are related to an economic outcome. These are similar to a cost-effectiveness analysis (see Table 3.2). For example, the mental health issues following chronic pain, inability to return to the workforce for a patient or informal carers, and the resultant isolation and psychological distress are all non-monetary considerations. Monetary considerations of pain outcomes can be considered either from the health system or patient perspective, depending on whether the issue in question is the impact of pain on the individual or the health systems. From an individual perspective, out-of-pocket costs, travel, parking and accommodation for rural patients are considerations, particularly for those with chronic pain. From the health system perspective, cost includes Medicare costs such as the Pharmaceutical Benefits Scheme (PBS) or Medicare Benefits Scheme (MBS), outpatient visits, as well as other hospital costs.

The pattern of opioid prescribing (dose, duration and type) while in hospital and after discharge are significant instigators of opioid misuse and its resultant economic burden (Neuman 2019 **NR**; Lowenstein 2018 **NR**; Shah 2017 **Level IV**). This important public health problem can be mitigated by appropriate acute pain strategies in the hospital setting. These may include analgesic techniques that minimise the dose and duration of opioid use; this includes using non-opioid analgesic strategies. At the time of patient discharge there needs to be appropriate limitations on the dose and duration of the prescribed opioids (Lowenstein 2018 **NR**) (see Sections 8.13 and 10.4.5). The estimated financial cost of prescription opioid misuse in Australia comprises the costs related to deaths, hospitalisation, and pharmacotherapy. The estimated annual (2018) costs of these three areas are $4.7 billion, $13.4 million and $60.2 million respectively (Deloitte Access Economics 2019). These costs may be further mitigated by a real-time prescription monitoring program which can reduce deaths and the issue of multiple prescribers ("*doctor shopping*") (Finklea 2014 **NR**; Winters 2013 **NR**).

A systematic review of patient outcomes after epidural analgesia showed a reduction in the incidence of costly adverse events. These included a reduced risk of atrial fibrillation, supraventricular tachycardia, deep vein thrombosis, respiratory depression, atelectasis, pneumonia, ileus, postoperative nausea and vomiting and improved recovery of bowel function (Popping 2014 **Level I** [PRISMA], 125 RCTs, n=9,044) (see section 5.6). These must be balanced against the increase in adverse events associated with epidural analgesia such as hypotension, pruritus, urinary retention and motor block.

One study examined the effect on patient outcome when an APS provided additional advice on patient care during their usual ward round (Story 2006 **Level III-3**, n=590). Examples of advice include oxygen therapy, IV fluid management, physiotherapy, analgesia, or calling the medical emergency team. This APS intervention resulted in a reduction of serious adverse events (from 23 to 16 per 100 patients) and reduced 30 d mortality (9% to 3%).

Chronic postsurgical pain (CPSP) has a significant prevalence, which is typically 1 to 10% at one year after surgery. This is dependent on the nature of surgery. A consistent predictor for the development of CPSP is the severity and duration of postoperative pain. The provision of effective acute pain management can reduce this costly public health problem. Examples include limb amputation, thoracotomy, craniotomy, joint arthroplasty, breast surgery and inguinal hernia repair. (Glare 2019 **NR**). Once CPSP is established, it may be challenging to treat, resulting in ongoing costs. Additionally, there are indirect costs, including impairment of return to employment. The annual cost per patient (2018) with chronic pain was estimated at A$42,979 (Deloitte Access Economics 2019 **NR**). A potential strategy to reduce the transition from acute to chronic postsurgical pain, along with its economic costs, is the use of a transitional pain clinic. Patients at this clinic are reviewed and managed in the early period after hospital discharge to prevent the progression from acute to chronic pain and reduce opioid usage (Huang 2016 **Level IV**; Katz 2015 **NR**) (see also Section 1.4).

Quantifying the health outcomes of patients immediately after surgery as well as over the longer term will allow improved assessments of cost-effectiveness of new strategies.

KEY MESSAGES

1. Long term economic consequences from the progression of acute to chronic postsurgical and post-traumatic pain can be significant (**S**) (**Level IV**).
2. Strategies to optimise acute and subacute pain management (including involvement of transitional pain services) may reduce the economic burden of chronic pain and inappropriate prescription opioid use (**N**) (**Level IV**).
3. The early pattern of prescription opioid use after surgery may increase the risk of chronic use with significant direct and indirect economic costs (**N**) (**Level IV**).
4. Patients' willingness to pay for good pain relief is high (**S**) (**Level IV**).
5. Costs from PCA errors can be considerable; the most common high cost errors arise from staff communication error and operator error (**S**) (**Level IV**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ There are different measures of economic assessment and analysis used in healthcare; no one method is the most appropriate (**U**).

☑ Prescription drug monitoring may reduce the economic burden through its impact on inappropriate opioid prescribing (**N**).

4.1 | Paracetamol

Paracetamol and its intravenous prodrug propacetamol are the only remaining aniline derived drugs used in clinical practice; it is an effective analgesic (see below) and antipyretic. It is absorbed rapidly and well from the small intestine after oral administration with a bioavailability of between 63 and 89% (Oscier 2009 **NR**). It can also be given rectally and IV (see below and Chapter 5).

4.1.1 | Mechanism of action

Despite extensive use since its discovery in the 19th century the mechanism of action of paracetamol is still not fully understood. In contrast to opioids, paracetamol has no known endogenous binding sites and, unlike NSAIDs, causes only weak inhibition of peripheral cyclooxygenase (COX) activity, with apparent selectivity for COX-2 (Graham 2013a **NR**). Given its limited peripheral actions the most likely mechanism is a central effect and may involve multiple pathways:

- When paracetamol is de-acetylated to p-aminophenol it can undergo conjugation with arachidonic acid by fatty acid amide hydrolase to AM404 in the CNS (Ghanem 2016 **NR**). AM404 has multiple potential mechanisms of action in the CNS. Firstly, it is a weak cannabinoid receptor agonist as well as a reuptake inhibitor of the endocannabinoid anandamide. Secondly, it is a potent TRPV1 receptor agonist and a TRPV1 mutation is associated with paracetamol non-responsiveness in healthy humans volunteers (Pickering 2020 **Level II EH**, n=47, JS 4);
- Paracetamol has been shown to prevent prostaglandin production at the cellular transcriptional level predominantly in the CNS, independent of COX activity (Mancini 2003 **BS**). This may also be AM404 mediated as AM404 reduces PGE-2 release from activated microglia (Saliba 2017 **BS**). This effect is independent of cannabinoid and TRPV1 receptor effects;
- Indirect effects on the serotonergic system appear to be important. In volunteers, coadministration of tropisetron or granisetron blocked the analgesic effects of paracetamol (Pickering 2008 **EH**; Pickering 2006 **EH**). In children undergoing tonsillectomy who all received paracetamol, a fixed dose of morphine and betamethasone, administration of ondansetron was associated with significantly more morphine in recovery vs droperidol, but no change in codeine over the first 24 h (Ramirez 2015 **Level II**, n=69, JS 4).

4.1.2 | Efficacy

For paediatric specific information see 10.4.1.1

Perioperative use

Single doses of paracetamol are effective in the treatment of postoperative pain. The NNTs for a variety of doses, as well as combinations of paracetamol with other analgesic medicines such as codeine, are discussed in Chapter 5 and listed in Table 5.1.

There is no good evidence for a dose-dependent analgesic effect of oral paracetamol; the effects of 500 mg (NNT 3.5; 95%CI 2.7 to 4.8), 600/650 mg (NNT 4.6; 95%CI 3.9 to 5.5) and 1,000 mg (NNT 3.6; 95%CI 3.2 to 4.1) show no statistically significant difference (Moore 2015b **Level I** [Cochrane], 53 RCTs, n=5,679). Although in clinical practice there is no clear evidence of a dose-response relationship, experimental surgical models have shown that the maximal

effective dose is 1000 mg. Paracetamol by all routes of administration has an opioid-sparing effect on PCA-morphine consumption (MD over 24 h -6.3 mg; 95%CI -9.0 to -3.7), although this effect is inferior to nsNSAIDs and coxibs (Maund 2011 **Level I**, 60 RCTs, n unspecified).

Oral paracetamol given 1 h prior to surgery reduced the pain intensity of propofol injection: by a median NRS of 2/10(IQR 0 to 3) for 500 mg and 4/10 (2 to 5) for 1,000 mg vs placebo 8/10 (7 to 10) (Nimmaanrat 2019 **Level II**, n=324, JS 5).

IV paracetamol is also an effective analgesic after surgery with an NNT of 4.0 (95%CI 3.5 to 4.8) over 4 h and an NNT of 5.3 (95%CI 4.2 to 6.7) over 6 h (Tzortzopoulou 2011 **Level I** [Cochrane], 36 RCTs, n=3,896). When paracetamol is used as an adjuvant to opioid analgesia, opioid requirements are reduced by 30% over 4 h after a single IV dose. For hip and knee arthroplasty, there is a reduction in pain scores for each of the first 3 PODs (POD 1: WMD -0.95; 95%CI -1.2 to -0.7) and opioid consumption (POD 1: WMD -3.1; 95%CI -4.1 to -2.1) (Yang 2017a **Level I** [PRISMA], 4 RCTs, n=865).

IV paracetamol given perioperatively reduces PONV when administered before recovery from anaesthesia (Apfel 2013 **Level I** [PRISMA], 30 RCTs, n=2,364). This effect is correlated to pain relief achieved, but not to reduced opioid consumption. IV paracetamol given before incision is more effective than post incision in reducing pain at 1 h (MD -0.50; 95%CI -0.98 to -0.02) and 2 h (MD -0.34; 95%CI - 0.67 to -0.01), 24 h opioid consumption (SMD 0.52; 95%CI -0.98 to -0.06) and PONV (RR 0.50; 95%CI 0.31 to 0.83) (Doleman 2015b **Level I** [PRISMA], 7 RCTs, n=544).

Other acute pain indications

Paracetamol is superior to placebo for migraine (NNT 12 for pain-free response at 2 h) and reaches the efficacy of sumatriptan when combined with 10 mg metoclopramide (Derry 2013a **Level I** [Cochrane], 11 RCTs, n=2,942). In episodic tension-type headache (TTH), paracetamol is mildly effective at 2 h (NNT for mild pain or pain free 10; 95%CI 7.9 to 14) (Stephens 2016 **Level I** [Cochrane], 23 RCTs, n=8,079). Paracetamol is also superior to placebo for postpartum perineal pain (OR 2.14; 95%CI 1.59 to 2.89) (Chou 2013 **Level I**, 10 RCTs, n=1,377) but less effective than NSAIDs (Wuytack 2016 **Level I** [Cochrane], 3 RCTs, n=342). Paracetamol does not appear to be effective for acute low back pain (Saragiotto 2016 **Level I** [Cochrane], 3 RCTs, n=1,825).

Paracetamol in combinations

The combination of paracetamol and NSAIDs is more effective than either paracetamol or NSAID alone (Martinez 2017 **Level I** [NMA], 2 RCTs, n=85 [paracetamol/NSAID]; 60 RCTs, n=3,259 [NSAIDs]; 20 RCTs, n=699 [paracetamol]; Ong 2010 **Level I**, 21 RCTs, n=1,909). This in particular is shown for the combination of paracetamol and ibuprofen in the setting of wisdom tooth removal (Bailey 2013 **Level I** [Cochrane], 7 RCTs, n=2,241).

A combination of 1,000 mg paracetamol with 130 mg caffeine is more effective than paracetamol alone (OR 1.12; 95%CI 1.05 to 1.19) in a range of painful conditions with no safety concerns (Palmer 2010 **Level I** [QUOROM], 8 RCTs, n=2,510).

Combinations of paracetamol with opioids such as codeine, tramadol or hydrocodone show increased efficacy (see Section 5.1.3.1.).

4.1.3 | Adverse effects

For paediatric specific information see 10.4.1.3

Paracetamol has fewer adverse effects than NSAIDs and can be used when the latter are contraindicated (eg patients with a history of renal impairment, asthma or peptic ulcers).

4.1.3.1 | Hepatic effects

The risk of hepatotoxicity from therapeutic doses (maximum 4 g/24 h) is not supported by current data (Dart 2007 **Level IV SR**, 791 studies, n=40,202). The higher number of findings in the retrospective vs the prospective studies suggests that some of these cases may be inadvertent overdoses. Similar safety has also been shown in a paediatric population with no cases of liver disease, need for antidote or transplantation, or death (95%CI 0.000 to 0.009) and only 0.031% of cases (95%CI 0.015 to 0.057) with major or minor hepatic adverse effects (Lavonas 2010 **Level IV SR**, 62 studies, n=32,414). In conclusion, hepatotoxicity from therapeutic doses of paracetamol is extremely rare (Caparrotta 2018 **NR**; Graham 2013a **NR**).

Guidelines based on individual case reports only recommend that paracetamol should be used with caution or in reduced doses in patients with low body weight (<50 kg), active liver disease, history of heavy alcohol intake, older age, malnutrition, Gilbert's syndrome and glucose-6-phosphate dehydrogenase deficiency (NPS MedicineWise 2015 **GL**; Queensland Health 2014 **GL**; NSW TAG 2008 **GL**); however, consistent evidence of increased risk in these settings is lacking (Caparrotta 2018 **NR**; Graham 2013a **NR**). Therapeutic doses of paracetamol are an unlikely cause of hepatotoxicity in patients who ingest moderate to large amounts of alcohol. In subjects who consume alcohol, no elevation of alanine aminotransferase levels was noted with up to 4 g/d of paracetamol for at least 4 d (Rumack 2012 **Level I** [PRISMA], 5 RCTs, n=551); no cases of hepatic failure or death were observed in any published prospective trial of moderate to heavy alcohol drinkers. In patients newly abstinent after abusing alcohol, therapeutic doses of paracetamol had no effect on parameters of liver function (Dart 2010 **Level II**, n=142, JS 5).

There is no evidence that patients who have depleted glutathione stores (eg patients who are malnourished or who have cirrhosis, hepatitis C or HIV) are at increased risk of liver dysfunction when exposed to therapeutic doses of paracetamol (Caparrotta 2018 **NR**; Graham 2013a **NR**). However, there is a potential association between acute liver failure and therapeutic paracetamol doses in paediatric patients with myopathies (Ceelie 2011 **Level IV**, n=2).

Paracetamol overdose is a common cause of acute liver failure (Caparrotta 2018 **NR**; Graham 2013a **NR**); in the USA 30,000 patients are hospitalised every year for paracetamol overdose, of which >50% are unintentional and 17% result in hepatotoxicity (Blieden 2014 **NR**). In a multiethnic Asian population, the hepatotoxicity rate was lower at 7.3% (Marzilawati 2012 **Level IV**, n=1,024). Treatment should be with acetylcysteine; there is no obvious advantage of IV over oral administration (Green 2013 **Level III-3 SR**, 16 studies, n=5,164). Treatment delays increase the incidence of hepatotoxicity; a detailed systematic review on interventions for treatment of paracetamol poisoning (Chiew 2018 **Level I** [Cochrane], 11 RCTs, n=700) and treatment guidelines have been published (Chiew 2020 **GL**).

4.1.3.2 | Renal effects

Newly diagnosed chronic kidney disease patients had an increased risk of end-stage renal disease with paracetamol use (OR 2.92; 95%CI 2.47 to 3.45) and higher risk with increasing dose exposure (Kuo 2010 **Level III-2**, n=19,163).

4.1.3.3 | Cardiovascular effects

There is a potential association between premature closure of ductus arteriosus and maternal paracetamol use in pregnancy (Allegaert 2019 **Level IV SR**, 12 studies, n=25). Given paracetamol has been shown to be as effective as ibuprofen for closure of a patent ductus arteriosus in preterm neonates (Ohlsson 2018 **Level I** [Cochrane], 8 RCTs, n=916), it seems reasonable to recommend that (as with all medications) use should be limited to the minimum dose and duration that is clinically necessary.

The overall effect of oral paracetamol on long term blood pressure remains unclear; observational studies (4 studies, n=155,910) show a variable association between paracetamol use and increased hypertension, but RCTs (6 RCTS, n=152) have inconsistent results (Turtle 2013 **Level III-3 SR**, 6 RCTs and 4 studies, n=156,062).

Paracetamol may interact with warfarin to increase the International Normalised Ratio (INR) (Hughes 2011 **Level IV SR**, 5 studies (& 5 case reports), n=345; Pinson 2013 **Level IV SR**, 6 studies (& 2 case reports); n=365) (5 studies and 2 case reports overlap).

For information on IV paracetamol and hypotension of see Section 5.2.1.

4.1.3.4 | Respiratory effects

In children, exposure to paracetamol was associated with an increased incidence of asthma (pooled OR 1.63; 95%CI 1.46 to 1.77) (Etminan 2009 **Level III-3 SR**, 19 studies, n=425,140). There are also claimed associations between the use of paracetamol in pregnancy and subsequent asthma in childhood (OR 1.19; 95%CI 1.12 to 1.27) (Fan 2017 **Level III-3 SR**, 13 studies, n=1,043,109). For details see Section 10.4.1.3.

4.1.3.5 | Carcinogenic effects

A review of epidemiological studies of paracetamol and cancer found mixed studies with respect to renal cell carcinoma and very limited positive studies with plasma cell disorders and leukaemia and otherwise a null effect on other types of cancer (Weiss 2016 **NR**).

4.1.3.6 | Neurodevelopmental effects

Epidemiological studies show an association between attention deficit disorder and paracetamol usage in pregnancy: for longer >29 d (HR 2.2; 95%CI 1.50 to 3.24), but not short duration use <8 d (HR 0.90; 95%CI 0.81 to 1.00) (Ystrom 2017 **Level III-3**, n=112,973). For details see Section 9.1.1.1 and 10.4.1.3.

Caution should be used with interpretation of all these retrospective analyses because of the possible effect of unknown or unmeasured confounding factors; the relevance to use limited to an acute situation is also unclear.

KEY MESSAGES

1. Paracetamol is an effective analgesic for acute pain; the incidence of adverse effects is comparable to placebo (**U**) (**Level I** [Cochrane Review]).
2. Paracetamol given in addition to PCA opioids reduces opioid consumption but does not result in a decrease in opioid-related adverse effects (**U**) (**Level I**).
3. Hepatotoxicity with therapeutic doses of paracetamol is extremely rare (**U**) (**Level IV**) and not associated with alcohol consumption (**U**) (**Level I** [PRISMA]).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Emerging evidence suggests that maternal paracetamol use may influence premature closure of the fetal ductus arteriosus **(N).**

4.2 | Nonselective NSAIDs and coxibs

4.2.1 | Systemic nonselective nonsteroidal anti-inflammatory drugs

The term NSAIDs refers to both nonselective NSAIDs (nsNSAIDs) and coxibs (COX-2 selective inhibitors). NSAIDs have a spectrum of analgesic, anti-inflammatory and antipyretic effects and are effective analgesics in a variety of acute pain states. Many effects of NSAIDs can be explained by inhibition of prostaglandin synthesis in peripheral tissues, nerves and the CNS (Botting 2006 **NR**). However, NSAIDs and aspirin may have other mechanisms of action independent of any effect on prostaglandins, including effects on basic cellular and neuronal processes. Prostaglandins are produced by the enzyme prostaglandin endoperoxide synthase, which has both COX and hydroperoxidase sites. Subtypes of the COX enzyme have been identified; the "constitutive" COX-1 and the "inducible" COX-2; COX-3 does not appear to play a significant role in fever or inflammation in humans (Kam 2009 **NR**; Botting 2006 **NR**; Gajraj 2005 **NR**; Simmons 2004 **NR**).

Prostaglandins regulate many physiological functions including gastric mucosal protection, bronchodilation, renal tubular function and intrarenal vasodilation. Production of endothelial prostacyclin leads to vasodilation and prevents platelet adhesion, whereas thromboxane, produced from platelets by COX, results in platelet aggregation and vasoconstriction. With the exception of prostacyclin synthesis (mediated largely through COX-2), such physiological roles are mainly regulated by COX-1 and this is the basis for many of the adverse effects associated with nsNSAID use. Tissue damage induces COX-2 production leading to synthesis of prostaglandins that result in inflammation, peripheral sensitisation of nociceptors and consequently increased pain perception. COX-2 induction within the spinal cord plays a role in central sensitisation. COX-2 may also be "constitutive" in some tissues, including the kidney, cardiovascular system and brain and is overexpressed in some cancers (Kam 2009 **NR**).

NSAIDs are reversible COX inhibitors with the exception of aspirin, which binds covalently and acetylates the enzyme irreversibly. In platelets, the enzyme cannot be replenished leading to prolonged inhibition of platelet function with minimal inhibition of endothelial prostacyclin; this confers cardiovascular protection at low dosages of aspirin. NsNSAIDs are "nonselective" COX inhibitors that inhibit both COX-1 and COX-2. The coxibs have been developed to inhibit selectively, but not specifically, COX-2 (Botting 2006 **NR**; Gajraj 2005 **NR**; Simmons 2004 **NR**).

4.2.1.1 | Efficacy

Single doses of oral nsNSAIDs are effective in the treatment of pain after surgery (Moore 2015b **Level I** [Cochrane], RCTs ≈460, n≈50,000). For a list of NNTs for each medicine see Table 5.1. However, while useful analgesic adjuvants, they are often inadequate as the sole analgesic agent in the treatment of severe postoperative pain (Cepeda 2005 **Level II**, n=1,003, JS 5).

They are also effective analgesics in chronic low-back pain (Enthoven 2016 **Level I** [Cochrane], 13 RCTs, n= 4,807), renal colic (Afshar 2015 **Level I** [Cochrane], 50 RCTs, n=5,734), primary dysmenorrhoea (Marjoribanks 2015 **Level I** [Cochrane], 80 RCTs, n=5,820), migraine (Rabbie 2013 **Level I** [Cochrane], 9 RCTs, n=4,473); Derry 2013b **Level I** [Cochrane], 5 RCTs, n=1,356), acute ankle sprains (van den Bekerom 2015 **Level I**, 28 RCTs, n unspecified), biliary colic (Colli 2012 **Level I**, 11 RCTs, n=1,076) and acute muscle injury (Morelli 2018 **Level I** [PRISMA], 41 RCTs, n= 5,343).

For more information on use in migraine see Section 8.6.5.2 and in paediatrics Section 10.9.3.

Nonselective NSAIDs are integral components of multimodal analgesia (Young 2012 **NR**; Buvanendran 2009 **NR**; Kehlet 1997 **NR**). When given in combination with IV PCA morphine after surgery, nsNSAIDs result in better analgesia, reduced opioid consumption (MD over 24 h -10.2 mg; 95%CI -11.7 to -8.7) and a lower incidence of PONV (OR 0.70; 95%CI 0.53 to 0.88) (Maund 2011 **Level I**, 60 RCTs, n unspecified). Similar findings were made in the paediatric setting (Michelet 2012 **Level I**, 27 RCTs, n=985).

The combination of paracetamol and NSAIDs is more effective than paracetamol or NSAID alone (Martinez 2017 **Level I** [NMA], 2 RCTs, n=85 [Paracetamol/NSAID]; 60 RCTs, n=3,259 [NSAIDs]; 20 RCTs, n=699 [paracetamol]; Ong 2010 **Level I**, 21 RCTs, n=1,909). This is particularly well documented for the combination of paracetamol and ibuprofen in the setting of wisdom tooth removal (Bailey 2013 **Level I** [Cochrane], 7 RCTs, n=2,241).

Administration of ketorolac to patients with rib fractures reduced the incidence of pneumonia (OR 0.14; 95%CI 0.04 to 0.46) and reduced requirements for ICU admission and ventilation (Yang 2014 **Level III-2**, n=619). The perioperative use of nsNSAIDs, predominantly rectal diclofenac and indomethacin, for endoscopic retrograde cholangiopancreatography (ERCP) reduces the risk of post-ERCP pancreatitis vs placebo (RR 0.54; 95%CI 0.45 to 0.64) (Liu 2019 **Level I** [PRISMA], 19 RCTs, n=5,031).

In cancer surgery, initial data suggested benefits of intraoperative use of nsNSAIDs in breast cancer patients (reduced recurrence rate and lower mortality) and in lung cancer patients (lower metastases risk and longer survival) (Forget 2013 **Level III-2**, n=720). In breast cancer surgery, intraoperative administration of nsNSAIDs (ketorolac or diclofenac) was associated with an improved disease-free survival (HR 0.57; 95%CI 0.37 to 0.89) and better overall survival (HR 0.35; 95%CI 0.17 to 0.70) (Forget 2014 **Level III-2**, n=720). However, a more recent case control study found a reduction of distant recurrences with ketorolac, but not diclofenac (Desmedt 2018 **Level III-2**, n=1,834). Despite epidemiological associations with NSAIDs reducing prostate cancer risk, pre-operative courses of celecoxib 400mg BD did not appear to increase tumor cell apoptosis in surgical specimens (Flamiatos 2017 **Level II**, n=28, JS 5). NSAID administration (primarily ibuprofen) after colorectal surgery was associated with reduced recurrence in a historical case series (aHR 0.84; 95%CI 0.72 to 0.99) (Schack 2019 **Level III-3**, n=2,308).

4.2.1.2 | Adverse effects

Adverse effects of nsNSAID are more common with long-term use; the major concerns relate to the gastrointestinal, renal and cardiovascular systems. In the perioperative and acute period, the main concerns are renal impairment, interference with platelet function, wound and bone healing and peptic ulceration or bronchospasm in individuals at risk. Certain risks are accentuated in the perioperative period because of pre-existing comorbidities, concurrent medications, haemodynamic disturbances, fluid shifts, activation of the neurohumoral stress response and deficient enteral feeding.

In general, the risk and severity of nsNSAID-associated adverse effects is increased in elderly people (Juhlin 2005 **Level II**, n=14, JS 4; Pilotto 2003 **Level III-2**, n=2,251). For this reason, opioids are sometimes used in preference to NSAIDs. A cohort study of elderly patients with arthritis (mean age 80 y) started on nsNSAIDs, coxibs or opioids challenges the assumption that opioids are safer in that population, showing increased rates of fracture, hospital admission and all-cause mortality in the opioid cohort and similar or higher rates of cardiovascular, renal and gastrointestinal adverse effects (Solomon 2010 **Level III-2**; n=12,840). Overall the nsNSAID cohort appeared to have the lowest risk for adverse effects.

Gastrointestinal effects

Chronic nsNSAID use is associated with peptic ulceration and bleeding and the latter may be exacerbated by the antiplatelet effect (Bhala 2013 **Level I**, 754 RCTs, n=353,809). All long-term nsNSAID regimens increase the risk of upper gastrointestinal complications (diclofenac RR 1.89; 95%CI 1.16 to 3.09; ibuprofen RR 3.97; 95%CI 2.22 to 7.10; naproxen RR 4.22; 95%CI 2.71 to 6.56). The combination of an nsNSAID with an SSRI further increases the risk of upper gastrointestinal bleeding (Anglin 2014 **Level III-2 SR**, 19 studies, n>393,268). In patients with rheumatoid arthritis, steroids and NSAIDs appear to be additive in increasing gastric ulceration (Tsujimoto 2018 **Level III-2**, n=1,704).

Acute gastroduodenal damage and bleeding can also occur with short-term nsNSAID use; the risk is increased with higher doses, a history of peptic ulceration, use for >5 d and in patients >75 years of age (Strom 1996 **Level III-3**, n=10,272 [uses of parenteral ketorolac]). After 6.5 d of naproxen and 5 d of ketorolac use in healthy elderly subjects (65 to 75 y of age), ulcers were found on gastroscopy in 18 and 23% of cases respectively (Goldstein 2003 **Level II**, n=168, JS 4; Stoltz 2002 **Level II**, n=94, JS 4; Harris 2001 **Level II**, n=17 [terminated due to high incidence of gastrointestinal ulcers in both nsNSAID groups], JS 4). Importantly, such endoscopic findings do not correlate with dyspeptic symptoms; these consequently cannot be relied upon as an indicator of potential harm (Dib 2014 **Level III-2**, n=1,231).

The relative risk of hospital admission for perforations, ulcers and bleeds associated with nsNSAIDs is estimated as 5.3 vs people not consuming nsNSAIDs (Lanas 2003 **Level III-2**, n=3,532). Use of ketorolac and piroxicam carried the highest risk. Concurrent use of a proton-pump inhibitor (PPI) significantly reduced the incidence of nsNSAID-related peptic ulcer disease (Targownik 2008 **Level III-2**, n=35,339). However, concurrent use of a PPI and nsNSAID (diclofenac) was still associated with an increased risk of clinically significant upper or lower gastrointestinal adverse effects vs coxib alone (RR 4.3; 95%CI 2.6 to 7.0) (Chan 2010b **Level II**, n=4,484, JS 5). Suppression of gastric acid by PPI to reduce nsNSAID-induced gastropathy may increase the risk of enteropathy lower in the gastrointestinal tract (Blackler 2014 **NR**), possibly from changes in gut flora (Minalyan 2017 **NR**).

Colonic diverticular bleeding is also increased by aspirin (RR 1.73; 95%CI 1.31 to 2.30) and other nsNSAIDs (RR 2.24; 95%CI 1.63 to 3.09) (Yuhara 2014 **Level III-2 SR**, 6 studies, n≈52,000).

Renal effects

Renal prostaglandins regulate tubular electrolyte handling, modulate the actions of renal hormones and maintain renal blood flow and glomerular filtration rate in the presence of circulating vasoconstrictors. The adverse renal effects of chronic nsNSAID use are common and well recognised. In some clinical conditions, including hypovolaemia, dehydration and major surgery, high circulating concentrations of the vasoconstrictors angiotensin II, noradrenaline and vasopressin increase production of intrarenal vasodilators including prostacyclin; maintenance of renal function may then depend on prostaglandin synthesis and thus can be sensitive even to brief nsNSAID administration (McDowell 2014 **NR**).

In patients with normal preoperative renal function, NSAIDs vs placebo may slightly increase serum creatinine (MD 3.23 micmol/L; 95%CI -0.80 to 7.26), however effects on acute kidney injury and need for renal replacement therapy are uncertain (Bell 2018 **Level I** [Cochrane], 26 RCTs, n=8,943). The risk of adverse renal effects of nsNSAIDs and coxibs is increased in the presence of factors such as pre-existing renal impairment, hypovolaemia, hypotension, use of other nephrotoxic agents including angiotensin-converting enzyme (ACE) inhibitors (Juhlin 2005 **Level II**, n=14, JS 4), IV contrast media and aminoglycosides (RCA 1998 **Level IV**). Of note, a trial of naproxen following cardiac surgery was stopped because of an increased rate of renal failure (7.3 vs 1.3%) (Horbach 2011 **Level II**, n=161, JS 5). This is confirmed by an analysis of a French pharmacovigilance database, which showed that acute renal failure caused by drug interactions between NSAIDs

and ACE inhibitors, angiotensin-receptor blockers or diuretics was a common issue (Fournier 2014 **Level IV**, n=11,442 [notifications of adverse drug reactions]).

After nephrectomies, evidence is limited and contradictory with a continuous infusion of ketorolac for 24 h after laparoscopic donor nephrectomy having no significant effect on renal function for up to 18 mth postoperatively (Grimsby 2014 **Level II**, n=111, JS 3), but a retrospective case series of donor nephrectomies found a reduction in renal function at 12 mth despite less pain and a shorter LOS (Takahashi 2017 **Level III-2**, n=251). Another retrospective case series found no associations at 1 wk, 1 y or 5 y (Tabrizian 2019 **Level III-2**, n=862).

In the PRECISION trial, long-term use of ibuprofen for treatment of arthritis was associated with significantly more serious renal events than celecoxib (HR 0.61; 95%CI 0.44 to 0.85), but not naproxen (HR 0.79; 95% CI, 0.56 to 1.12) (Nissen 2016 **Level II**, n=24,081, JS 5).

Overall in the general population, NSAID (including coxib) usage is associated with an increased risk of AKI (OR 1.73; 95%CI 1.44 to 2.07) as well as exacerbation in patients with CKD (OR 1.63; 95%CI 1.22 to 2.19) (Zhang 2017a **Level III-3 SR**, 10 studies, n=1,609,163).

For more information on paediatric effects see Section 10.4.2.3.

Cardiovascular effects

Most publications looking at the risk of cardiovascular adverse effects associated with nsNSAID use also include information relating to risks with coxibs (see the more detailed discussion under Section 4.3.2 below).

For some years it has been known that ibuprofen may impede access of aspirin to platelet COX-1 and may abrogate the protective effect of aspirin (Hudson 2005 **Level III-2**, n=18,503; MacDonald 2003 **Level III-2**, n=7,107). Subsequent research indicates that a degree of inhibition may occur with most nsNSAIDs and even some coxibs; while not blocking COX-1, they may block aspirin from reaching it (Nalamachu 2014 **NR**). This is backed up by an ad hoc analysis of PRECISION trial data which showed worse cardiovascular outcomes of aspirin/ibuprofen vs aspirin/celecoxib (HR 1.27; 95%CI 1.06 to 1.51) (Reed 2018 **Level III-2**, n=23,953). Impaired aspirin inhibition of platelet function is described in multiple studies for ibuprofen, flufenamic acid, mefenamic acid, piroxicam, nimesulide and dipyrone, while there is conflicting evidence with respect to naproxen, celecoxib, rofecoxib and sulindac, and no inhibition was seen with diclofenac, etoricoxib, ketorolac, ketoprofen, meloxicam or paracetamol (Polzin 2013 **Level III-2**; Meek 2013 **EH**; Saxena 2013 **EH**). The FDA issued a caution specifically about the concomitant use of aspirin and ibuprofen, which states that ibuprofen should be "*given at least 8 hours before or at least 30 minutes after immediate release aspirin*" (FDA 2006 **GL**).

Platelet effects and bleeding

Nonselective NSAIDs inhibit platelet function on aggregometry with naproxen and ibuprofen showing a mild antiplatelet effect for up to 72 and 48 h respectively where meloxicam and celecoxib show essentially no antiplatelet activity (Scott 2014 **BS**).

More recent studies and meta-analyses seem to show less impact of perioperative nsNSAIDs on bleeding compared to older ones, perhaps reflecting improvements in surgical technique and reduced total blood loss. A recent meta-analysis found no increased haematoma risk in plastic surgery (OR 1.39; 95%CI 0.82 to 2.37) (Walker 2019 **Level I** [PRISMA] 15 studies, n=3,064) and in another meta-analysis ketorolac did not increase the rate of postoperative bleeding (OR 1.1; 95%CI 0.61 to 2.06) (Gobble 2014 **Level I**, 27 RCTs, n=2,314). In a cohort study in paediatric neurosurgery, ketorolac was not associated with an increase in clinically significant bleeding events (OR 0.69; 95%CI 0.15 to 3.1) or radiographic haemorrhage (OR 0.81; 95%CI 0.43 to 1.51) (Richardson 2016 **Level III-2**, n=1,451). In contrast, in a previous meta-analysis the rate of surgery-related bleeding was 2.4% after nsNSAIDs vs 0.4% with placebo (Maund 2011 **Level I**, 6 RCTs [bleeding], n=695). In another meta-analysis the use of nsNSAIDs showed a significant increase in

risk of severe bleeding from 0 to 1.7% vs placebo (NNH 59) (Elia 2005 **Level I**, 52 RCTs, n=4,893). A retrospective analysis using data from 2003 to 2016 looking at transfusion risk for hip fractures found a small increase in risk of transfusion with preoperative nsNSAID use within 90 d of surgery (RR 1.07; 95%CI 1.04 to 1.10) (Glassou 2019 **Level III-2**, n=74,791). Other older evidence showing an increased risk of bleeding includes ibuprofen in total hip arthroplasty (THA) (Fransen 2006 **Level II**, n=902, JS 5), tenoxicam in otorhinolaryngological surgery (Merry 2004 **Level II**, n=1,001, JS 5) and diclofenac vs rofecoxib in gynaecological and breast surgery (Hegi 2004 **Level II**, n=50, JS 5).

Bleeding after tonsillectomy is of clinical significance but occurs infrequently; nsNSAID use and post tonsillectomy bleeding remains controversial with conflicting evidence. The most recent meta-analysis found no statistically significant increase of any outcome related to bleeding with the perioperative use of nsNSAIDs in tonsillectomy (Riggin 2013 **Level I**, 36 RCTs, n=3,193). This was found for most severe bleeding outcome (OR 1.30; 95%CI 0.90 to 1.88), bleeding requiring reoperation (OR 1.32; 95%CI 0.59 to 2.95), bleeding requiring readmission (OR 1.08; 95%CI 0.54 to 2.15), bleeding managed conservatively (OR 1.56; 95%CI 0.91 to 2.66) and secondary haemorrhage (OR 0.90; 95%CI 0.40 to 2.01). There is also no increased bleeding outcome in the paediatric subgroup of this meta-analysis (19 RCTs, n=1,747), which is in line with another meta-analysis in children only (OR 1.69; 95%CI 0.71 to 4.01) (Lewis 2013 **Level I** [Cochrane], 15 RCTs, n=1,101) (see also Section 10.4.2.3 for details). However, neither of these meta-analyses include a subsequent multicentre RCT which was unable to show non-inferiority of ibuprofen to paracetamol with respect to bleeding requiring surgery in paediatric patients (1.2% vs 2.9%; p=0.12 for noninferiority) (Diercks 2019 **Level II**, n=741, JS 5). The above meta-analysis (Riggin 2013 **Level I**, 46 RCTs, n=4,878) could not identify a specific risk for any nsNSAID including aspirin (OR 4.23; 95%CI 0.64 to 27.66) (3 RCTs, n=1,610) and ketorolac (OR 2.01; 95%CI 0.62 to 6.54) (8 RCTs; n=579). These findings are contradicted by a previous larger meta-analysis on aspirin (OR 1.94; 95%CI 1.09 to 3.42) (Krishna 2003 **Level I**, 7 RCTs, n=1,368) and a systematic review on ketorolac (Chan 2014 **Level III-2 SR** [PRISMA], 10 studies, n=1,357). The latter found an overall increased risk of bleeding post tonsillectomy with ketorolac (RR 2.04; 95%CI 1.32 to 3.15), which was also found in adults (RR 5.64; 95%CI 2.08 to 15.27) (3 studies, n=246) but not in children (RR 1.39; 95%CI 0.84 to 2.30) (7 studies, n=1,111).

For more information on paediatric effects see Section 10.4.2.3 and on post-tonsillectomy pain see Sectioin 8.6.7.3.

Hypersensitivity and NSAID-exacerbated respiratory disease (NSAID-ERD)

NSAIDs, especially nsNSAIDs, are one of the most common causes of drug-induced hypersensitivity reactions. Acute reactions include rhinitis, asthma, urticaria, angioedema and anaphylaxis, while delayed reactions include fixed drug eruptions, Stevens-Johnson syndrome, toxic epidermal necrolysis, maculopapular reactions, pneumonitis, nephritis or aseptic meningitis (Kowalski 2019 **GL**). This guideline advises on classification, diagnosis and management.

NSAID-ERD has a community prevalence of 1.8% and affects 10-20% of adults with asthma and 5% of children with asthma (Kowalski 2019 **GL**). Bronchospasm usually occurs within 1 to 2 h of exposure and precipitation is related to COX-1 activity, while both COX-2 selective NSAIDs (eg celecoxib and etoricoxib) and COX-2 preferential inhibitors (eg nimesulide and meloxicam) being usually well tolerated. See also Section 4.2.2.2 below.

Bone and ligament healing

Ever since the first study in 1976 showed impaired osteoblastic activity with indomethacin in rodent bone models of fracture there has been concern about the effect of NSAIDs on bone healing. The most recent meta-analysis of cohort studies shows an association between long-term NSAID usage and delayed union or disunion (OR 2.07; 95%CI 1.19 to 3.61), but not with low dose or short duration (<2 wk) (OR 1.68; 95%CI 0.63 to 4.46) or in paediatric populations (OR

0.58; 95%CI 0.27 to 1.21) (Wheatley 2019 **Level III-2 SR**, 19 studies, n=15,242 bones). Given the non-randomised cohort nature of this evidence, it may be that patients are taking NSAIDs for longer for a painful non-healing fracture rather than NSAIDs being a causative agent and a firm conclusion is unlikely without a large and well-designed randomised control trial.

In a meta-analysis which included primarily anterior cruciate ligament (ACL) reconstructions (93%) no difference in surgical failure was seen (3.6 vs 3.7%) (Constantinescu 2019 **Level III-2 SR**, 4 studies, n=4,451)

Anastomotic leakage and colorectal surgery

Rodent models of anastomotic leakage have for some time shown reduced collagen formation in rodents given diclofenac leading to concerns about the effect of NSAIDs on anastomotic leak rate in humans (Klein 2012 **BS**). The two most recent meta-analyses of primarily cohort studies show an increased anastomotic leak rate with nsNSAIDs (OR 2.02; 95%CI 1.62 to 2.50 and OR 1.79; 95%CI 1.47 to 2.18 respectively) (Modasi 2019 **Level III-2 SR** [PRISMA], 8 studies, n=9,835; Huang 2018 **Level III-2 SR**, 17 studies, n=26,098) (4 studies overlap). Subgroup analysis was unable to show any increase with either selective COX-2 inhibitors (OR 1.17; 95%CI 0.50 to 2.74) or ketorolac (OR 1.36; 95%CI 0.89 to 2.06)). A high risk of publication bias was detected.

NSAIDs do, however, improve recovery of gastrointestinal function with evidence for faster return of flatus (MD -17.73 h; 95%CI -21.26 to -14.19), stool passage (MD -9.52 h; 95%CI -14.74 to -4.79), and oral feeding tolerance (MD -12.00 h; 95%CI -18.01 to -5.99 h) (Chapman 2019 **Level I** [PRISMA], 6 RCTs, n=563). NSAIDs also reduce the recurrence rate of colorectal adenomas after endoscopic resection (RR 0.68; 95%CI 0.63 to 0.73) (Wang 2015a **Level I**, 9 RCTs, n=8,521).

Central nervous system effects

CNS effects of NSAIDs are poorly defined, but range from symptomatic adverse effects such as headache or dizziness through to possible disease modification in conditions such as Parkinson's disease and dementia (Auriel 2014 **NR**). Evidence on effects on cognitive decline is conflicting with long-term NSAID use showing a small protective effect in one metanalysis of cohort studies (RR 0.87; 95 %CI 0.81 to 0.94) (Wang 2016b **Level III-2 SR** [PRISMA], 11 studies, n=36,165), but no protective effect in another looking at low dose aspirin (Veronese 2017 **Level III-2 SR** [PRISMA], 3 RCTs & 5 studies, n=36,196).

4.2.2 | Systemic cyclooxygenase-2 selective inhibitors (Coxibs)

Coxibs selectively inhibit the inducible COX enzyme, COX-2, and relatively spare constitutive COX-1 (see above). The coxibs available at present are celecoxib, etoricoxib, polmacoxib and parecoxib (the injectable prodrug of valdecoxib). By sparing physiological tissue prostaglandin production while inhibiting inflammatory prostaglandin release, coxibs offer the potential for effective analgesia with fewer adverse effects than nsNSAIDs. However, as noted above, some constitutive physiological synthesis of prostaglandins is also mediated through COX-2, and coxibs may still inhibit COX-1 to some extent.

4.2.2.1 | Efficacy

Coxibs are as effective as nsNSAIDs for postoperative pain (Moore 2015b **Level I** [Cochrane], ≈460 RCTs, n≈50,000), osteoarthritis of the knee (Smith 2016 **Level I** [PRISMA], 9 RCTs, n= 2,937) and chronic low-back pain (Chung 2013 **Level I** [PRISMA], 25 RCTs, n=5,935). NNTs are comparable to those for nsNSAIDs for the treatment of moderate to severe acute pain. For a list of NNTs for each mediciation see Table 5.1.

When given in combination with opioids after surgery, coxibs show reduced opioid consumption similar to nsNSAIDs (MD over 24 h -10.9 mg; 95%CI -12.8 to -9.1) but no significant reductions in pain scores or opioid-related adverse effects (Maund 2011 **Level I**, 60 RCTs, n unspecified). When given as a single dose preoperatively, coxibs provide a reduction in mean postoperative analgesic requirements at 24 h (MD -0.68; 95%CI -0.95 to -0.33) (Nir 2016 **Level I** [PRISMA], 13 RCTs, n=1,079).

After total knee arthroplasty (TKA), use of coxibs in the perioperative period reduces pain scores, opioid consumption, PONV and pruritus and improves range of motion without increased blood loss (Lin 2013 **Level I**, 8 RCTs, n=571). Continuation of coxibs for 6 wk postoperatively resulted in ongoing improved analgesia and reduced opioid consumption with improved rehabilitation conveying benefits on knee flexion for up to 1 y (Schroer 2011 **Level II**, n=107, JS 5). The risk-benefit ratio for coxibs as a discharge medication after orthopaedic surgery is superior to that for nsNSAIDs (Roberts 2012 **Level I** [PRISMA], 23 RCTs, n unspecified).

Pain relief at rest and on movement and satisfaction were improved when oral celecoxib was added to thoracic PCEA using local anaesthetic and opioid (Senard 2010 **Level II**, n=40, JS 5).

Celecoxib given pre-operatively is effective at reducing 24 h parenteral MED consumption (MD 4.13 mg; 95%Cl 5.58 to 2.67), pain scores at 24 h (MD -1.02/10; 95%CI -1.54 to -0.50) and reducing postoperative nausea and vomiting by 44% and 38% respectively (Khan 2016 **Level I**, 14 RCTs, n=994).

A meta-analysis of parecoxib in orthopaedic surgery in elderly patients shows a reduction in perioperative cognitive dysfunction up to 7 d (RR 0.32; 95%CI 0.16 to 0.63), but not at 3 mth (RR 0.40; 95%CI 0.16 to 1.02) (Huang 2019 **Level I** [PRISMA], 2 RCTs, n=200); these results should be viewed with caution as outcome measures were not robust. A similar effect was shown with celecoxib after arthroplasty (Zhu 2018b **Level II**, n=178, J 5).

4.2.2.2 | Adverse effects

Gastrointestinal effects

In the PRECISION trial, celecoxib/esomeprazole was associated with significantly less gastrointestinal events than ibuprofen/esomeprazole (HR 0.43; 95%CI 0.27 to 0.68) and naproxen/esomeprazole (HR 0.51; 95%CI 0.32 to 0.81) (Yeomans 2018 **Level II**, n=24,081, JS 5). Despite a possible dosing inequality this is supported by a trial of naproxen 500 mg BD + PPI vs Celecoxib 100 mg BD + PPI in patients with a recent GI bleed (Chan 2017 **Level II**, n=514, JS 5). Rebleed rates were 5.6% (95%CI 3.3 to 9.2) in the celecoxib group and 12.3% (95%CI 8.8 to 17.1) in the naproxen group (HR 0.44; 95%CI 0.23 to 0.82). Etoricoxib in osteoarthritis similarly shows superiority to nsNSAIDs in terms of GI event rates (RR 0.67; 95%CI 0.59 to 0.76) (Feng 2018 **Level I** [PRISMA], 9 RCTs, n=39,442).

Short-term use (< 7 d) of parecoxib/valdecoxib, as required to treat acute pain, results in gastroscopic ulcer rates similar to placebo in elderly patients (65 to 75y) at increased risk (Goldstein 2003 **Level II**, n=168, JS 4; Stoltz 2002 **Level II**, n=94, JS 4; Harris 2001 **Level II**, n=17 [terminated due to high incidence of gastrointestinal ulcers in both nsNSAID groups], JS 4). This contrasts with increased rates of ulceration with nsNSAIDs in the same setting.

Despite relative safety in comparison to nsNSAIDs, long term usage of COX-2 inhibitors is still associated with an increased GI event rate in cohort studies of non-use versus etoricoxib (RR 4.85; 95%CI 2.64 to 8.93), rofecoxib (RR 2.02; 95%CI 1.56 to 2.61) and celecoxib (RR 1.53; 95%CI 1.19 to 1.97) (Martin Arias 2019 **Level III-2 SR** [PRISMA], 28 studies, n=1,255,401). These results might be unexpected given that both rofecoxib and etoricoxib are more COX-2 selective than celecoxib, however current understanding of gastrointestinal injury includes multiple mechanisms such as mitochondrial uncoupling and ion-trapping that may be unrelated to COX inhibition (Bjarnason 2018 **NR**). In a pooled analysis of COX-2 inhibitor use in osteoarthritis an increase in

gastrointestinal events is seen vs placebo (RR 1.19, 95% CI 1.03 to 1.38) (Curtis 2019 **Level I** [PRISMA], 40 RCTs, n unspecified).

Renal effects

COX-2 is constitutively expressed in the kidney and is highly regulated in response to alterations in intravascular volume. COX-2 has been implicated in maintenance of renal blood flow, mediation of renin release and regulation of sodium excretion (Cheng 2004 **NR**; Kramer 2004 **NR**).

A meta-analysis of perioperative parecoxib found no increase in renal failure vs placebo (Schug 2017 **Level I**, 26 RCTs, n=9,282). In contrast (and as with nsNSAIDs), a statistically significant increased risk of renal failure was reported following administration of coxibs in cardiac surgery patients (NNH 73) (Elia 2005 **Level I**, 3 RCTs [cardiac surgery], n=803).

In the PRECISION trial, long-term ibuprofen was associated with significantly more serious renal events than celecoxib (HR 0.61; 95%CI 0.44 to 0.85), but naproxen was not worse than celecoxib (HR 0.79; 95%CI 0.56 to 1.12) (Nissen 2016 **Level II**, n=24,081, JS 5).

Analysis of the effects of different coxibs on renal function showed heterogeneity within the class as rofecoxib was associated with increased risk of renal dysfunction, while celecoxib was not (Zhang 2006 **Level I**, 114 RCTs, n=116,094).

A subsequent meta-analysis of cohort studies of the general population showed little evidence of lower AKI incidence with increasing COX-2 selectivity (OR 1.84; 95%CI 1.54 to 2.19 [no COX-2 selectivity] vs OR 1.41; 95%CI 1.07 to 1.87 [≥5 fold COX-2 selectivity]) (Zhang 2017a **Level III-2**, 10 studies, n=1,609,163).

Cardiovascular effects

Cardiovascular risk with coxibs seems very dependent on the coxib in question. This may reflect non-COX dependent effects that NSAIDs may have on the cardiovascular system (Walker 2018 **NR**).

In acute pain management, short-term use of parecoxib (< 7 d) after noncardiac surgery does not increase the risk of cardiovascular adverse effects (Schug 2017 **Level I**, 26 RCTs, n=9,282). Similarly, short-term use of other NSAIDs (meloxicam, ketorolac, celecoxib for a mean of 3 d) after lower limb total joint replacement did not increase the risk of myocardial infarction postoperatively vs nonuse (aOR 0.95; 95%CI 0.5 to 1.8) (Liu 2012 **Level III-2**, n=10,873). However, an increase in the incidence of cerebrovascular and cardiovascular events has been reported in patients given parecoxib, then valdecoxib, after CABG surgery (Furberg 2005 **Level I**, 2 RCTs, n=2,098). The FDA has contraindicated the use of all NSAIDs in the immediate postoperative period following CABG surgery (FDA 2007 **GL**). A subsequent retrospective observational study with ketorolac has not confirmed these concerns (Oliveri 2014 **Level III-2**, n=1,309).

Absolute long-term cardiovascular risk with chronic usage of NSAIDs remains unclear as the recent large prospective studies were non-inferiority trials without a placebo arm. Studies are conflicting as to cardiovascular risk with individual drugs.

In a review of epidemiological data, rofecoxib showed increased cardiovascular risks vs other coxibs and nsNSAIDs (Gunter 2017 **Level III-2 SR**, 26 studies, n=228,389). In the PRECISION trial in patients with arthritis, there was no difference in cardiovascular event rates between long-term celecoxib vs ibuprofen (HR 0.81; 95%CI 0.65 to 1.02) or vs naproxen (HR 0.90; 95%CI 0.71 to 1.15) (Nissen 2016 **Level II**, n=24,081, JS 5). The SCOT trial randomised patients over 60 y with arthritis to either continue their current NSAID or be changed to celecoxib and found no difference in cardiovascular risk (HR 1.1; 95%CI 0.81 to 1.55) (MacDonald 2017, **Level II**, n=7,297, JS 3).

A Bayesian meta-analysis found no increased risk of myocardial infarction for celecoxib (OR 1.24; 95%CI 0.91 to 1.82) or ibuprofen (OR 1.48; 95%CI 1.00 to 2.26), but increased risk for diclofenac (OR 1.50; 95%CI 1.06 to 2.04), naproxen (OR 1.53; 95%CI 1.07 to 2.33) and rofecoxib

(OR 1.58; 95%CI 1.07 to 2.17) (Bally 2017 **Level III-2**, n=446,763 [61,460 myocardial infarctions]). This data directly conflicts with a previous meta-analysis that found no increased cardiovascular risk with naproxen, diclofenac or etoricoxib (Trelle 2011 **Level I**, 31 RCTs, n=116,429).

Once daily administration of celecoxib eg 400 mg (RR 1.1; 95%CI 0.6 to 2.0) was associated with a lower cardiovascular risk than giving 400 mg as divided doses of 200 mg twice daily (RR 1.8; 95%CI 1.1 to 3.1) (Solomon 2008 **Level I**, 6 RCTS, n=7,950).

All NSAIDs approximately double the risk of congestive heart failure (Bhala 2013 **Level I**, 54 RCTs, n=353,809). However, this analysis pooled all coxib data so that data from rofecoxib and celecoxib was not differentiated. A subsequent meta-analysis of coxibs which looked at heart failure in osteoarthritis found no increase in congestive heart failure (RR 1.18; 95%CI 0.24 to 5.71) (4 RCTs), but increased risk of peripheral oedema (RR 1.61; 95%CI 1.09 to 2.40) (15 RCTs) and generalised oedema (RR 1.91; 95%CI 1.08 to 3.39) (8 RCTs) (Curtis 2019 **Level I** [PRISMA], 40 RCTs, n unspecified). In a nested cohort study which matched 92,163 heart failure admissions with 8,246,403 controls, all NSAIDs except celecoxib were associated with an increased risk of heart failure (Arfe 2016 **Level III-2**, n=8,566,955).

A small increase in the risk of atrial fibrillation with NSAID usage (RR 1.12; 95%CI 1.06 to 1.18) has been documented (Krijthe 2014, **Level III-2**, n=8,423).

In comparison with a historical cohort, the use over a subsequent 10 mth period of parecoxib and valdecoxib 40 mg daily for 2 to 3 wk was associated with an increase in the rate of vascular free flap failure from 7 to 29%, which fell to 4% after the coxibs were no longer used (Al-Sukhun 2006 **Level III-3**, n=180). These retrospective data, which are subject to potential confounding factors, are supported by one study in rats showing a harmful effect of parecoxib on flap survival (Ren 2013 **BS**), which did not occur with celecoxib (Wax 2007 **BS**). A retrospective cohort study using ketorolac after head and neck free flaps found no bleeding complications and no increased risk of free flap failure (Schleiffarth 2014 **Level III-2**, n=138 [free flaps]).

Platelet effects and bleeding

Platelets express only COX-1, not COX-2, and as a consequence, coxibs do not impair platelet function (Munsterhjelm 2006 **Level II EH**, n=18, JS 4). This is consistent with a study on platelet aggregometry with meloxicam and celecoxib show essentially no antiplatelet activity (Scott 2014 **BS**). COX-2 selective NSAIDs show no difference in the risk of postoperative bleeding events (RR 0.92; 95%CI 0.63 to 1.33), intraoperative blood loss (WMD -4.38 mL; 95%CI -14.69 to 5.92), postoperative blood loss (WMD -13.89 mL; 95%CI -30.24 to 2.47), and 24 h postoperative haemoglobin loss (WMD 0.47 g/dL; 95%CI 0.14 to 1.09) vs nsNSAIDs, other analgesics, or placebo (Teerawattananon 2017 **Level I**, 16 RCTs, n=1,704).

Allergic reactions and NSAID-exacerbated respiratory disease

Patients with anaphylactoid reactions to dipyrone and nsNSAIDs (mainly propyphenazone and diclofenac) tolerated oral challenges with rofecoxib and celecoxib (Quiralte 2004 **Level IV**, n=33).

Coxibs, administered at analgesic doses, do not produce bronchospasm in patients with NSAID-exacerbated respiratory disease (Morales 2013 **Level I** [PRISMA], 14 RCTs, n=426).

Bone and ligament healing

At present, data on the effect of coxibs on bone healing are mainly restricted to animal models, where they undoubtedly affect bone remodelling (Kurmis 2012 **NR BS**). Celecoxib after THA reduced the frequency and severity of heterotopic bone formation (Lavernia 2014 **Level III-2**, n=170**;** Oni 2014 **Level III-2**, n=214). There is no good evidence of any clinically significant inhibitory effect of coxibs on bone healing (Kurmis 2012 **NR**; Gerstenfeld 2004 **NR**; Bandolier 2004 **NR**).

In a small single centre trial, re-tear rates were increased following rotator cuff repairs in celecoxib(11/30 [37%]) vs ibuprofen (2/27 [7%]) and tramadol treated patients (1/25 [4%]) groups (Oh 2018 **Level II**, n=180, JS 5). This matches animal model data from rabbits (Lu 2015 **BS**).

Anastomotic leakage

There is no increased leakage rate with perioperative coxibs (Modasi 2019 **Level III-2 SR** [PRISMA], 8 studies, n=9,835; Huang 2018 **Level III-2 SR**,17 studies, n=26,098) (4 studies overlap). See 4.2.1.2 for more detail.

KEY MESSAGES

Efficacy of systemic NSAIDs

1. Nonselective NSAIDs are effective in the treatment of acute postoperative pain, renal colic, migraine, primary dysmenorrhoea (**S**) (**Level I** [Cochrane Review]), acute muscle injury (**N**) (**Level I** [PRISMA]), chronic low-back pain (**U**) (**Level I** [PRISMA]) and acute ankle sprain (**U**) (**Level I**).
2. Coxibs are as effective as nonselective NSAIDs in the treatment of acute pain (including postoperative pain) (**S**) (**Level I** [Cochrane Review]), chronic low-back pain (**U**) (**Level I** [PRISMA]) and osteoarthritis of the knee (**N**) (**Level I** [PRISMA]).
3. Nonselective NSAIDs given in addition to paracetamol improve analgesia compared with either medicine given alone (**S**) (**Level I**), in particular ibuprofen combined with paracetamol (**U**) (**Level I** [Cochrane Review]).
4. The risk-benefit ratio for coxibs as a discharge medication after orthopaedic surgery is superior to that for nonselective NSAIDs (**U**) (**Level I** [PRISMA]).
5. Nonselective NSAIDs given in addition to PCA opioids reduce opioid consumption and the incidence of nausea and vomiting (**U**) (**Level I**).
6. Coxibs given in addition to PCA opioids reduce opioid consumption but do not result in a decrease in opioid-related adverse effects (**U**) (**Level I**), except after total knee arthroplasty, where they reduce pain scores and adverse effects and improve outcomes (**U**) (**Level I**).
7. Celecoxib given as a single pre-operative dose is effective at reducing opioid usage, pain scores at 24 hours and postoperative nausea and vomiting (**N**) (**Level I**).

Adverse effects of systemic NSAIDs

8. In patients with normal preoperative renal function nonselective NSAIDs slightly increase serum creatinine, but effects on acute kidney injury and need for renal replacement therapy are uncertain due to lack of evidence (**W**) (**Level I** [Cochrane Review]).
9. Nonselective NSAIDs may increase the risk of any bleeding-related outcome after tonsillectomy in adults (**U**) (**Level I**); however, not in paediatric patients (**U**) (**Level I** [Cochrane Review]) except in a large non-inferiority RCT where need for surgical intervention was increased with ibuprofen versus paracetamol (**Q**) (**Level II**). There is an increase in bleeding complications with aspirin in adults and children (**U**) (**Level I**) and with ketorolac in adults only (**U**) (**Level III-2** [PRISMA]).
10. Nonselective NSAIDS, but not coxibs, may cause bronchospasm in individuals known to have NSAID-exacerbated respiratory disease (**U**) (**Level I** [PRISMA]).
11. Coxibs and nonselective NSAIDs exert individual (non-class) adverse effects on the cardiovascular system with rofecoxib appearing to be worse than other coxibs and nonselective NSAIDs (**N**) (**Level I**). Celecoxib is no worse than naproxen or ibuprofen (**N**) (**Level II**) and better than ibuprofen when combined with aspirin (**N**) (**Level II**).

12. Short-term use of parecoxib (**S**) (**Level I**) and other NSAIDs (**U**) (**Level III-2**) compared with placebo does not increase the risk of cardiovascular adverse effects after noncardiac surgery.
13. Use of parecoxib followed by valdecoxib after coronary artery bypass graft surgery increases the incidence of cardiovascular and cerebrovascular effects and is therefore contraindicated (**U**) (**Level I**).
14. Perioperative nonselective NSAIDs may increase the risk of minor and major bleeding after surgery compared with placebo (**W**) (**Level I**).
15. Coxibs do not impair platelet function and are not associated with increased perioperative blood loss (**S**) (**Level I**).
16. In patients with normal renal function, parecoxib perioperatively does not increase renal failure (**N**) (**Level I**).
17. NSAIDs hasten bowel recovery after colorectal surgery (**N**) (**Level I**).
18. With regard to renal function, celecoxib and naproxen are safer than ibuprofen with long-term use (**N**) (**Level II**).
19. Short-term use (5–7 days) of coxibs results in gastric ulceration rates similar to placebo and lower than nonselective NSAIDs (**U**) (**Level II**).
20. The cardiovascular protective effects of low-dose aspirin are reduced by concomitant administration of some NSAIDs, in particular ibuprofen (**S**) (**Level II**).
21. Nonselective NSAIDs, but not coxibs increase the risk of anastomotic leak after colorectal surgery (**N**) (**Level III-2**).
22. Short term use of ketorolac or ibuprofen do not increase bone healing complications in children undergoing posterior spinal fusion, osteotomy, or fractures managed surgically (**S**) (**Level III-3**) or conservatively (**N**) (**Level III-3**).
23. Chronic administration of nsNSAIDs or coxibs is associated with an increased risk of renal impairment (**N**) (**Level III-3 SR**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ The risk of adverse renal effects of nonselective NSAIDs and coxibs may be increased in the presence of factors such as pre-existing renal impairment, hypovolaemia, hypotension and use of other nephrotoxic agents including angiotensin-converting enzyme inhibitors (**W**).

4.2.3 | Nonsystemic administration of nonsteroidal anti-inflammatory drugs

Non-systemic (transdermal patch or gel, wound infiltration) for non-ophthalmic (intra- or abdominal wall, mastectomy and skin graft) surgery as part of multimodal analgesic regimens may improve pain control and postoperative function vs placebo or systemic administration based on low to moderate quality evidence (Brubaker 2016 **Level I** [PRISMA], 9 RCTs, n=532).

4.2.3.1 | Intra-articular

Following arthroscopy, intra-articular (IA) nsNSAIDs (tenoxicam and ketorolac) result in improved pain relief (Romsing 2000 **Level I**, 16 RCTs, n=844 [7 RCTs IA]). Compared with systemic administration, IA nsNSAIDs (4 RCTs) showed a pain reduction of 20/100 (95%CI 13 to 26) and a 50 to 65% reduction in supplementary analgesic requirements over 24 h. In contrast, when IA nsNSAIDs were compared with IA placebo, two of three RCTs showed no significant analgesic benefit. More recent studies do not permit differentiation of the effect of IA NSAIDs from other components in the injected solution.

In human chondrocytes, single-dose equivalent concentrations of ketorolac caused significant chondrotoxicity (Abrams 2017 **BS**). Intraarticular ketorolac for THA showed no increased risk of prosthetic loosening, even with long-term follow-up (mean 7.3 y) (Nizam 2015 **Level IV**, n=100).

4.2.3.2 | Wound infiltration

Infiltration of the surgical wound with local anaesthetic/nsNSAID vs local anaesthetic and IV nsNSAID showed no difference in analgesia in three of five RCTs (overall WMD -6/100; 95%CI -19 to 6); similarly, wound infiltration with local anaesthetic/nsNSAID vs local anaesthetic/ placebo showed no analgesic benefit in four of five studies (Romsing 2000 **Level I**, 16 RCTs, n=844 [10 RCTs wound]). This lack of a local effect was confirmed with lornoxicam after thyroidectomy (Kilbas 2015 **Level II**, n=80, JS 4).

4.2.3.3 | Local infiltration analgesia

Local infiltration analgesia (LIA) involves the intraoperative periarticular infiltration of large volumes of local anaesthetic combined with a variety of adjuvants typically including an alpha-2 agonist/vasoconstrictor, an opioid and/or an anti-inflammatory agent. The majority of investigations into the effectiveness of LIA in acute pain management following THA/TKA fail to separate out the components of the mixture and some protocols also use catheter-based “top-up” regimens of varying composition. The lack of appropriate systemic comparators further complicates analysis of the role of the individual components. Ketorolac is the most frequently used nsNSAID in the LIA mixture. A systematic review identified no RCTs enabling a comparison of the efficacy of systemic vs periarticular administration of nsNSAIDs as a component of LIA in THA (Andersen 2014a **Level I** [PRISMA], 27 RCTs [THA], n=756).

The peak plasma concentrations of ketorolac after use of 30 mg as a component of LIA were comparable to those of similar doses administered IM (0.3-2.2 mg/L) (Affas 2014 **PK**).

4.2.3.4 | Intravenous regional analgesia

Ketorolac 60 mg in combination with local anaesthetic for IV regional analgesia (IVRA) demonstrated longer time to first analgesia request vs local anaesthetic IVRA with either IV ketorolac or IV placebo following minor upper limb procedures (Reuben 1995 **Level II**, n=60, JS 2).

However, pain scores were low overall and this study was not blinded. Ketorolac 60 mg added to local anaesthetic for IVRA or infiltrated into the wound provided superior analgesia for up to 2 h following tourniquet release vs no ketorolac use (Reuben 1996 **Level II**, n=60, JS 3). Again, pain scores were low for all groups and there was no separate parenteral ketorolac arm for comparison. When varying doses of ketorolac were added to IVRA for hand surgery, a linear dose-response relationship from 5 to 20 mg was found; between 20 and 60 mg, there appeared to be no additional analgesic benefit (Steinberg 1998 **Level II**, n=75, JS 3). With IVRA doses of ≥20 mg vs doses <20 mg, time to first analgesia was prolonged and pain scores were lower for up to 2 h following tourniquet release. There was no comparison with ketorolac administered as a separate parenteral dose.

Overall, no conclusion can be drawn regarding a specific benefit of adding ketorolac to IVRA over parenteral administration by a separate route.

4.2.3.5 | Nerve block

Parecoxib/ropivacaine improved quality and duration of brachial plexus block vs placebo/ropivacaine and ropivacaine/IV parecoxib (Liu 2013 **Level II**, n=150, JS 5).

4.2.3.6 | Topical

Application to skin

In adult patients with acute pain resulting from strains, sprains or sports injuries, topical diclofenac, ibuprofen, ketoprofen, piroxicam and indomethacin are effective vs placebo, whereas benzydamine is not better than placebo (Derry 2015a **Level I** [Cochrane] 61 RCTs, n=8,386). Topical compounds with good efficacy are diclofenac with an NNT (for 50% pain reduction over placebo) of 3.7 (95%CI 3.2 to 4.3), ketoprofen of 3.9 (95%CI 3.0 to 5.3), piroxicam of 4.4 (95%CI 3.2 to 6.9) and ibuprofen of 4.6 (95%CI 3.3 to 8.0). Different formulations may differ in efficacy; gels seem to be superior to creams with a diclofenac gel preparation having the lowest NNT of 1.8 (95%CI 1.5 to 2.1) and ketoprofen gel one of 2.5 (95%CI 2.0 to 3.4). The rate of systemic adverse effects with the topical NSAIDs is low and does not differ from placebo. The rate was also lower than with the same NSAID by oral route, although there was limited data on direct comparison.

Topical NSAIDs were of limited efficacy in lateral elbow pain, providing short-term functional improvement for up to 2 wk (Pattanittum 2013 **Level I** [Cochrane], 8 RCTs, n=301). The overall quality of included studies was poor and findings heterogeneous. No comparisons with oral NSAIDs were included.

There is insufficient evidence to differentiate between routes of administration of NSAIDs in the treatment of acute low back pain (Roelofs 2008 **Level I** [Cochrane], 65 RCTs, n=11,237).

Topical application of diclofenac results in tissue levels that are higher and plasma levels that are lower vs oral administration (Zacher 2008 **Level I**, 19 RCTs, n>3,000). Topical NSAIDs were associated with fewer gastrointestinal adverse effects but more local skin irritation than systemic NSAIDs (Klinge 2013 **Level I**, 6 RCTs, n=600).

Ophthalmological applications

There is no strong evidence for pain reduction with topical NSAIDs for traumatic corneal abrasions, but some evidence for a reduced requirement for rescue analgesia at 24 h as a proxy for pain reduction (RR 0.46; 95%CI 0.34 to 0.61) (Wakai 2017 **Level I** [Cochrane], 9 RCTs, n=637). After cataract surgery, topical NSAIDs reduce anterior chamber inflammation and thereby provide postoperative analgesia (Duan 2017 **Level I** [PRISMA], 19 RCTs, n=7,234); diclofenac, nepafenac,

ketorolac and bromfenac are in particular effective. After a number of other ophthalmological procedures, multiple studies show contradictory results with topical NSAIDs.

Mucosal applications

Microgranules containing flurbiprofen 8.75 mg provided better pain relief and reductions in difficulty in swallowing for sore throat than placebo, with fast onset (1 min) and long duration (6 h) (Russo 2013 **Level II**, n=373, JS 5). Flurbiprofen spray (8.75 mg/dose) rapidly reduced symptoms of sore throat after upper respiratory tract infection and provided significantly more relief for up to 6 h vs placebo, with no difference in adverse effects vs placebo over 3 d (de Looze 2016 **Level II**, n=505, JS 5); similar results (non-inferior to the spray) were found with use of a 8.75 mg flurbiprofen lozenge (Radkova 2017 **Level II**, n=440, JS 5). Flurbiprofen was also useful in post-tonsillectomy pain with reduction in pain scores and reduced requirement for additional analgesia (Muderris 2016 **Level II,** n=84, JS 4).

KEY MESSAGES

1. Topical NSAIDs are effective in treating acute strains, sprains or sports injuries with systemic adverse effects comparable to placebo; gel formulations show superior efficacy over creams (**S**) (**Level I** [Cochrane Review]).
2. Topical NSAIDs are of limited analgesic efficacy for traumatic corneal abrasions, but reduce rescue analgesia requirements (**W**) (**Level I** [Cochrane Review]).
3. Topical NSAIDs reduce anterior chamber inflammation and thereby pain after cataract surgery (**N**) (**Level I** [PRISMA])**.**
4. The efficacy of NSAIDs for peri- or intra-articular injection as a component of local infiltration analgesia compared with systemic administration remains unclear (**U**) (**Level I** [PRISMA]).
5. Intra-articular nonselective NSAIDs may provide more effective analgesia following arthroscopy than intravenous administration (**U**) (**Level I**).
6. Mucosal administration of flurbiprofen provides long-lasting pain relief for sore throat (**N**) (**Level II**).

4.3 | Opioids

Opioids can bind to receptors in the brain, spinal cord and periphery, and can be administered systemically or locally (eg intrathecal, intra-articular).

4.3.1 | Systemic opioids

Opioids remain the mainstay of systemic analgesia for the treatment of moderate to severe acute pain.

While opioids are conventionally regarded as acting on opioid receptors, some opioids achieve analgesic effects by additional mechanisms or via alternate interactions with opioid receptors (Raffa 2014a **NR**). The first of this class to be labelled as an "atypical opioid" was tramadol with its effects on noradrenergic and serotonergic inhibitory systems on top of a weak mu-agonism (by an active metabolite) (Raffa 1992 **BS**). The term atypical opioids (although another term "multigesics" has also been suggested) (Pergolizzi Jr 2017 **NR**) is increasingly used for buprenorphine, cebranopadol, tapentadol and tramadol (Schug 2019 **NR**); of these cebranopadol is undergoing early clinical investigations (Lambert 2015 **NR BS**), while the other three are approved in many countries.

4.3.1.1 | Choice of systemic opioid

All full conventional opioid agonists can produce the same level or analgesia once the dose is appropriately adjusted (McQuay 1991 **NR**), although accurate determination of equianalgesic doses is difficult due to interindividual variabilities in kinetics and dynamics (Gammaitoni 2003 **NR**). Equianalgesic conversion dose tables are often used to assist in the change from one opioid to another. However, such tables are based largely on single-dose studies in opioid-naïve subjects and may not be as relevant when conversions are made after repeated doses of an opioid have been given (either in the acute or chronic pain setting) and do not consider incomplete cross-tolerance and patient-specific factors (Weschules 2008a **NR**). Care must be taken when opioid rotations are undertaken based on such tables alone without consideration of clinical factors because this carries a significant risk of toxicity and even fatality (Webster 2012 **NR**). When healthcare professionals (physicians, pharmacists, and nurse practitioners/physician assistants) were surveyed, there was a large variation in mean opioid conversions (Rennick 2016 **Level IV**, n=319). A detailed analysis of equianalgesic doses and suggestions for opioid rotations based on these calculations has been published (Treillet 2018 **Level IV SR**, 20 studies, n unspecified). FPMANZCA provides an opioid calculator including references and background material on a website (FPMANZCA 2019a **GL**), which is also available as an app ("Opioid Calculator") for smartphones. Opioid rotations to methadone require particular care due to the risk of accumulation and subsequent toxicity (McLean 2015 **Level IV SR**, 25 studies, n=1,229).

In general, there is little evidence, on a population basis, to suggest that there are any major differences in efficacy or the incidence of adverse effects between any of the pure agonist opioids, although the results of individual studies are inconsistent. However, for pharmacokinetic and other reasons, some opioids may be better in some patients (Woodhouse 1999 **Level II**, n=82, JS 4). Comparisons of the different opioids are commonly done in patients using PCA (see Section 6.3.1 for these comparisons).

While the data to support the concept of opioid rotation originate from cancer pain (Mercadante 2011 **Level III-2 SR**, 31 studies, n unspecified; Quigley 2004 **Level IV SR** [Cochrane], 52 studies, n unspecified), it may be a useful strategy in the management of acute pain in patients with

intolerable opioid-related adverse effects, who are unresponsive to treatment and in opioid-tolerant patients (see also Section 9.7).

The efficacy of various opioids administered by the different routes used in the management of acute pain is discussed in detail in Chapter 5. The following sections describe other relevant aspects of selected atypical and conventional opioids.

4.3.1.2 | Conventional opioids

Codeine

Codeine is classified as a weak opioid. However, it is only a very weak mu-receptor agonist and its analgesic action depends on the metabolism of about 10% of the dose to morphine, via the CYP2D6 cytochrome P450 isoenzyme (Lotsch 2005 **NR**). The principal metabolite of codeine is codeine-6-glucuronide, which has a similar low potency to the parent medicine and is renally excreted.

Over 100 allelic variants of CYP2D6 have been identified, resulting in wide variability in enzyme activity (Somogyi 2007 **NR**). Individuals carrying two wild-type alleles display normal enzyme activity and are known as extensive metabolisers; intermediate metabolisers are heterozygotes with two variant alleles known to decrease enzymatic capacity; and poor metabolisers have no functionally active alleles and have minimal or no enzyme activity (Stamer 2007a **NR**). In Caucasian populations, 8 to 10% of people are poor metabolisers; however, 3 to 5% are ultrarapid metabolisers (Madadi 2009 **Level III-2**, n=72; Stamer 2007a **NR**). Those who are ultrarapid metabolisers (carriers of the *CYP2D6* gene duplication) have significantly higher levels of morphine and morphine metabolites after the same dose of codeine (Kirchheiner 2007 **Level IV**, n=23).

There are large interethnic differences in the frequencies of the variant alleles. For example, the proportion of ultrarapid metabolisers is higher (up to 29%) in Middle Eastern and Northern African populations and lower (0.5%) in Asians (Stamer 2007b **NR**); the proportion of poor metabolisers is lower in Asians and African Americans (Yee 2013b **Level IV**, n=75; Holmquist 2009 **NR**).

A case-control study including a case of a newborn dying while breastfed by a mother taking codeine has highlighted that breastfed infants of mothers who are ultrarapid metabolisers are at increased risk of life-threatening CNS depression (Madadi 2009 **Level III-2**, n=72). A number of similar cases have been reported and health professionals and mothers of breastfeeding infants should be aware of this risk (Madadi 2008 **Level IV**, n=35). CYP2D6 genotyping predicts subjects with reduced or increased metabolism to morphine but must be combined with additional phenotyping to accurately predict patients at risk of morphine toxicity (Lotsch 2009 **Level III-2**, n=57)

Death or OIVI has occurred after codeine treatment. Although rare, the risk is highest in children who are ultrarapid metabolisers, after they have undergone tonsillectomy, adenoidectomy, or both, as many of these have sleep-disordered breathing and are therefore more sensitive to opioids (Friedrichsdorf 2013 **Level IV**, n=3; Kelly 2012 **Level IV**, n=4; Racoosin 2013 **NR**). The USA Food and Drug Administration (FDA) now requires a boxed warning of the risk posed by codeine after a child has undergone tonsillectomy or adenoidectomy (FDA 2013 **GL**). The European Medicines Agency has responded similarly (EMA 2013 **GL**); as has the WHO in removing codeine from its tiered analgesic ladder for treatment of (persistent) pain in children (WHO 2012 **GL**). Guidelines on this issue have been published (Crews 2014 **GL**). See also Sections 1.7.3.2 and 10.4.4.5.

Dextropropoxyphene

Oral dextropropoxyphene 65 mg alone is a poorly effective analgesic in postoperative pain (NNT 7.7) (Collins 2000 **Level I** [Cochrane], 6 RCTs [dextropropoxyphene only], n=440). Dextropropoxyphene is often used in combination with paracetamol but this combination does not lead to better pain relief vs paracetamol alone and increases the incidence of dizziness (Li Wan Po 1997 **Level I**, 26 RCTs, n=2,231).

The use of this compound is discouraged, not only because of its low efficacy but also because of a number of risks related to its use (Barkin 2006 **NR**). These include QT-interval prolongation and possibility of Torsades des Pointes (TdP) and cardiogenic death. This is exacerbated by complex pharmacokinetics (particularly in the elderly) with the risk of accumulation of dextropropoxyphene and its metabolite nordextropropoxyphene, leading to CNS, respiratory and cardiac depression (Davies 1996 **NR**). However, in therapeutic doses (125±25 mg) no prolongation of the QT-interval >500 ms was observed (Keller 2018 **Level IV**, n=92).

In line with many other developed countries including New Zealand, the Therapeutics Goods Administration (TGA) in Australia decided in November 2011 to remove the registration of dextropropoxyphene (Buckley 2013 **NR**). Despite a number of appeals by the manufacturer, the medication has since been withdrawn from sale in Australia.

Diamorphine

Diamorphine (diacetylmorphine, heroin) is rapidly hydrolysed to monoacetylmorphine (MAM) and morphine (Miyoshi 2001 **NR**); diamorphine and MAM are more lipid-soluble than morphine and penetrate the CNS more rapidly. It is MAM and morphine that are thought to be responsible for the analgesic effects of diamorphine.

There was no difference between parenteral diamorphine and morphine in terms of analgesia and adverse effects after hip surgery (Robinson 1991 **Level II**, n=40, JS 4) and between parenteral diamorphine and pethidine for labour analgesia (Wee 2014 **Level II**, n=484, JS 4). Epidurally administered diamorphine resulted in a longer time to first PCA use and lower total 24 h morphine requirements vs the same dose given by intramuscular (IM) injection (Green 2007 **Level II**, n=60, JS 4). Intranasal (IN) diamorphine has been used as an analgesic for acute pain in children attending EDs (Kendall 2015 **Level IV**, n=226). Here peak morphine plasma concentrations were higher and occurred earlier when diamorphine was administered IV vs IN (Kidd 2009 **Level III-1**, n=24).

Dihydrocodeine

Dihydrocodeine is a semisynthetic derivative of codeine and has similar mu-opioid agonist activity. However, unlike codeine, inhibition of CYP2D6 by quinine does not alter its analgesic effect, even though the CYP2D6-dependent active metabolite, dihydromorphine, has a much higher mu-opioid receptor affinity than the parent medicine (Lotsch 2005 **NR**). Orally administered, it has around twice the potency of codeine and one-sixth the potency of morphine (Leppert 2010 **NR**).

Fentanyl

Fentanyl is a highly potent phenylpiperidine derivative, structurally related to pethidine. It is metabolised almost exclusively in the liver to minimally active metabolites. Less than 10% of unmetabolised fentanyl is renally excreted. Fentanyl is commonly used in the treatment of acute pain, especially when its lack of active metabolites and fast onset of action may be of clinical benefit (Grape 2010 **NR**). The fast onset is the result in particular of its high lipophilicity (octanol:water partition coefficient >700); this leads to a transfer half-life of 4.7 to 6.6 min between plasma and CNS (Lotsch 2013 **NR**) (see also Section 5.4.1). The pharmacokinetics of fentanyl are influenced by impaired liver function and CYP3A4 inhibitor and inducer use (Kuip 2017 **NR**). Data on fentanyl causing opioid-induced hyperalgesia (OIH) are limited and conflicting

with 4 RCTs supporting the induction and 2 RCTs opposing it (Lyons 2015 **Level I**, 6 RCTs, n=340).

There is insufficient evidence to judge the efficacy of fentanyl in neuropathic pain (Derry 2016b **Level I** [Cochrane], 1 RCT, n=163).

There is an increasing rate of fentanyl (and its analogues) abuse, primarily in the USA, but also now seen in other countries (Jannetto 2019 **NR**). This is paralleled by an increase in fentanyl overdose deaths; in the USA there was a 72% increase from 2014 to 2015 reaching 9,580 deaths caused by synthetic opioids, primarily fentanyl (including illicitly manufactured/non-pharmaceutical). The high mortality is partially due to admixture of fentanyl with other drugs of abuse, in particular heroin; sources are illegal importation and diversion of fentanyl-containing medication (Kuczynska 2018 **NR**). In 2015, a cluster of fentanyl-laced heroin deaths was reported in Melbourne, Australia, the first report of this nature outside North America (Rodda 2017 **Level IV**, n=9 [fentanyl related deaths out of ≈ 4,000 deaths investigated]).

Hydromorphone

Hydromorphone is a derivative of morphine that is approximately five times as potent as morphine. The main metabolite of hydromorphone is hydromorphone-3-glucuronide (H3G), a structural analogue of morphine-3-glucuronide (M3G). Like M3G (see below), H3G is dependent on the kidney for excretion, has no analgesic action and can lead to dose-dependent neurotoxic effects (Smith 2000 **NR**; Wright 2001 **NR**; Murray 2005 **NR**).

Hydromorphone is an effective opioid analgesic with similar efficacy and adverse effects as other strong opioids (Quigley 2002 **Level I** [Cochrane], 36 RCTs [acute pain], n=2,521). It provides slightly better clinical analgesia than morphine with similar adverse effects (Felden 2011 **Level I**, 8 RCTs, n=1,004). In cancer pain, its efficacy is similar to oxycodone and morphine (Bao 2016 **Level I** [Cochrane], 4 RCTs, n=504). There is insufficient evidence to judge the efficacy of hydromorphone in neuropathic pain (Stannard 2016 **Level I** [Cochrane], 4 RCT, n=604).

Methadone

Methadone is a synthetic opioid commonly used for the maintenance treatment of patients with an addiction to opioids and in patients with chronic non cancer and cancer pain. It is commercially available as a racemic mixture of R- and L-enantiomers but it is the R-enantiomer that is responsible for most, if not all, its mu-opioid receptor-mediated analgesic effects (Fredheim 2008 **NR**; Lugo 2005 **NR**).

It has good oral bioavailability (70 to 80%), high potency and long duration of action and a lack of active metabolites (Lugo 2005 **NR**). It is also a weak NMDA-receptor antagonist and monoamine (5HT and noradrenaline [norepinephrine]) reuptake inhibitor and has a long and unpredictable half-life (mean of 22 h; range 4 to 190 h) leading to an increased risk of accumulation (Weschules 2008b **NR**). Therefore, it is of limited use for acute pain treatment. Its use as an analgesic in general requires caution and guidelines have been published (ACMT 2016 **GL**). Recommendations include that it should not be prescribed on an as-needed basis, that the risk of overdose during the initial induction period for chronic use is high and that titration should be very slow. A baseline ECG and a follow-up ECG at 30 d should be obtained in patients at risk for QT prolongation (eg on other medications that prolong QT interval, with structural heart disease or a history of arrhythmias). Patients need extra education on potential risks of methadone treatment.

Dose conversion is complex and depends on many factors including absolute doses of other opioids and duration of treatment (McLean 2015 **Level IV SR**, 25 studies, n=1,229). In cancer pain management, methadone has similar analgesic effects to morphine (Nicholson 2017 **Level I** [Cochrane], 6 RCTs, n=388) (see also 10.4.4.9). There is very limited, very low-quality evidence supporting the efficacy and safety of methadone for chronic neuropathic pain (McNicol 2017 **Level I** [Cochrane], 3 RCTs, n=105).

Methadone is metabolised primarily by the cytochrome P450 group of enzymes, in particular 3A4 and to a lesser extent by CYP 1A2, 2D6, 2D8, 2C9/2C8, 2C19 and 2B6 (Kapur 2011 **NR**). Over 50 drug-drug interactions with methadone are described. Concurrent administration of other medicines that are CYP450 inducers may increase methadone metabolism and lower methadone blood levels (eg carbamazepine, rifampicin, phenytoin, St John's wort [*Hypericum perforatum*] and some antiretroviral agents) leading to potential reduced efficacy or even withdrawal. Conversely, medicines that inhibit CYP450 (eg other antiretroviral agents, some selective serotonin-reuptake inhibitors [SSRIs], grapefruit juice and antifungal agents) may lead to raised methadone levels and an increase in adverse effects or overdose (Fredheim 2008 **NR**) See also Section 8.6.8.2 for interactions in patients with human immunodeficiency virus (HIV).

Methadone use, but not use of other opioids, was associated with an increased incidence of hypoglycaemia in a dose-dependent fashion (for doses >80 mg/d OR 3.1; 95%CI 2.5 to 3.6) (Flory 2016 **Level III-2**, n=641). This was also found in an analysis of reports from the USA's Food and Drug Administration Adverse Event Reporting System, which showed an association between methadone use and hypoglycaemia in comparison to all other opioids except tramadol (Makunts 2019 **Level IV**, n=12,004,552).

High-dose methadone (eg >100 mg/d) has been associated with prolonged QT intervals and other cardiac complications: Torsade de pointes, changes in QT dispersion, pathological U waves, Taku-Tsubo syndrome (stress cardiomyopathy), Brugada-like syndrome, and coronary artery diseases (Alinejad 2015 **NR**) (see below Section 4.3.1.5).

In the setting of postoperative pain (spinal surgery), low-dose methadone was associated with high rates of postoperative complications with the use of a mean dose of 0.14 (±0.07) mg/kg (11.5±4.6 mg) in mostly non opioid naïve patients (72.3%) with BMI 30.3 (±0.9) (Dunn 2018 **Level IV**, n=1,478). Respiratory depression was recorded in 36.8%, hypoxemia in 79.8%, naloxone administered 2.3% and 1.5% required reintubation. QTc prolongation occurred in 58.8% and arrhythmias in 29.9% as well as two in-hospital deaths (0.14%). In contrast, a meta-analysis of small trials in various surgery types (cardiac, abdominal, hysterectomy, day case, orthopaedic, and spinal) of low to intermediate dose methadone 0.1 to 0.43 mg/kg vs morphine (7 RCTs), morphine and placebo (1 RCT), hydromorphone (1 RCT) and fentanyl (1 RCT) controls reported low power and did not detect a difference in risk for sedation (OR 0.62; 95% CI 0.27 to 1.45), respiratory depression/hypoventilation (OR 1.03; 95% CI 0.20 to 5.25) or hypoxaemia (OR 1.56, 95% CI 0.67 to 3.61) (D'Souza 2020 **Level I** [PRISMA], 10 RCTs, n=617). Current data are inadequate to support the routine use of long acting single intraoperative methadone doses in surgical patients where, as already emphasised, opioid requirements vary and titration is warranted. Further, large scale randomised trials are needed to overcome detection bias and define the efficacy and safety of both single and multiple low-dose methadone use in the perioperative period, with consideration of opioid naive and opioid tolerant patient groups (Murphy 2019 **NR**). The ANZCA position paper on the role of slow release (SR) opioid formulations in acute pain includes methadone due to its long half-life and recommends that its use should be avoided (ANZCA 2018 **GL**)

Morphine

Morphine remains the standard against which other opioids are compared. Morphine-6-glucuronide (M6G) and M3G, the main metabolites of morphine, are formed by morphine glucuronidation, primarily in the liver. M6G is a mu-opioid receptor agonist that crosses the blood-brain barrier more slowly than morphine (De Gregori 2012 **NR**). It contributes such a large extent to morphine analgesia in patients with both normal (85% of the effect after parenteral and up to 95% after oral administration) and impaired (98% of the effect) renal function, that morphine could be regarded as a prodrug to M6G (Klimas 2014 **NR**). M6G also has other morphine-

like effects including respiratory depression (van Dorp 2006b **NR**; Dahan 2008b **NR**). M3G has very low affinity for opioid receptors, has no analgesic activity and animal studies have shown that it may be responsible for the neurotoxic symptoms (not mediated via opioid receptors), such as hyperalgesia, allodynia and myoclonus, sometimes associated with high doses of morphine (Lotsch 2005 **NR**).

Clinical trials have investigated M6G as an analgesic agent after a variety of different types of surgery. It was more effective than placebo (Smith 2009 **Level II**, n=201, JS 4; Romberg 2007 **Level II**, n=42, JS 3) and in some trials as effective as morphine (Cann 2002 **Level II**, n=144, JS 4; Hanna 2005 **Level II**, n=100, JS 3), although withdrawal due to insufficient analgesia was higher in another (Binning 2011 **Level II**, n=249, JS 5); this is possibly due to a slower onset of effect of M6G. However, in the clinical setting of titration of IV morphine to postoperative analgesia, which is an effective approach to early postoperative pain (Aubrun 2012 **NR**), the kinetics of morphine and its metabolites had only limited value in explaining the analgesic effects of morphine (Hammoud 2011 **Level IV**, n=214).

Excellent pain relief was also obtained after IT administration of 100 or 125 mcg M6G in patients after hip replacement surgery, but there was a high incidence (10%) of late respiratory depression (9 to 12 h after the dose was given) requiring treatment with naloxone, and a high incidence of nausea (76 to 88%) and vomiting (60 to 64%) (Grace 1996 **Level II**, n=75, JS 5).

The incidence and severity of nausea and vomiting as well as the need for antiemetics was less with lV M6G than with IV morphine (Binning 2011 **Level II**, n=249, JS 5; Cann 2002 **Level II**, n=144, JS 4). In healthy volunteers, IV morphine 0.15 mg/kg and IV M6G 0.2 mg/kg resulted in similar reductions in ventilatory response to carbon dioxide (CO_2) (Romberg 2003 **Level III-1 EH**).

Both M6G and M3G are dependent on the kidney for excretion. Impaired renal function, the oral route of administration (first-pass metabolism), higher doses and increased patient age are predictors of higher M3G and M6G concentrations (Faura 1998 **Level IV PK SR**, 57 studies, n=1,232; Klepstad 2003 **Level IV**, n=300) with the potential risk of severe long-lasting sedation and respiratory depression.

There is insufficient evidence to judge the efficacy of morphine in neuropathic pain (Cooper 2017 **Level I** [Cochrane], 5 RCTs, n=236). Oral morphine is effective in treating cancer pain with similar efficacy vs other opioids (Wiffen 2016 **Level I** [Cochrane], 62 RCTs, n=4,241).

Oxycodone

Oxycodone is a semisynthetic opioid and directly contributes the majority of drug effect itself while being metabolised primarily to noroxycodone by CYP3A4 (≈45%) and by CYP2D6 to oxymorphone (≈19%) (Kinnunen 2019 **NR PK**). Oxymorphone is more potent than oxycodone as a mu-receptor agonist (14 times) and has a higher receptor affinity (40 times) and may contribute to the overall analgesic effect of oxycodone (Samer 2010b **Level II EH**, n=10 [5-arm cross over], JS 5); noroxycodone, the major metabolite, is only a weak mu-receptor agonist (Lalovic 2006 **NR**; Coluzzi 2005 **NR**).

The dependence of oxymorphone concentrations on CYP2D6 activity and its high potency explains the impact of CYP2D6 polymorphism on oxycodone's pharmacodynamics and pharmacokinetics (Samer 2010b **Level II EH**, n=10 [5-arm cross over], JS 5). Ultrafast metabolisers experience better analgesic effects and higher toxicity, while poor metabolisers experience less analgesic effect. However, in acute postoperative pain, CYP2D6 genotype had no influence on oxycodone requirements (Zwisler 2010 **Level III-3**, n=270; Crews 2014 **GL**).

These findings mean also that drug-drug interactions can influence the efficacy of oxycodone (Samer 2010a **Level II EH**, n=10 [cross over], JS 5). This is particularly true for CYP2D6 ultrafast metabolisers but also can be influenced by CYP3A inhibitors such as ketoconazole, which increases the efficacy and toxicity of oxycodone. Therefore, use of a CYP3A inhibitor in an ultrafast CYP2D6 metaboliser is a potentially dangerous combination.

Animal studies have shown that oxycodone is actively taken up into the brain, resulting in a brain concentration that is up to six times that of free plasma levels (Bostrom 2008 **PK**); this may explain the discrepancies between its poorer mu-receptor affinity compared to morphine but its higher potency (Olkkola 2013 **NR**). In general anaesthesia, oxycodone showed a significant dose-dependent respiratory depressant effect measured by reduced minute ventilation, which was significantly more than that of comparable doses of morphine (Chang 2010 **Level II**, n=54, JS 4).

Overall oxycodone has a faster onset of action than morphine, better oral bioavailability, longer duration of action, fewer concerns about metabolites and a lower rate of adverse effects (Olkkola 2013 **NR**). There is increasing use of oxycodone in the perioperative setting based on these pharmacological properties (Kokki 2012 **NR**). With regard to analgesic efficacy in acute pain, IV oxycodone seems superior to fentanyl (6 RCTs) and sufentanil (2 RCTs) and comparable to morphine (3 RCTs), but these results may partially reflect use of doses which were not equianalgesic (Raff 2019 **Level I**, 11 RCTs, n=721). The incidence of adverse effects was lower with oxycodone vs fentanyl (possibly also a reflection of non-equianalgesic doses) and comparable for oxycodone vs morphine and sufentanil. Patient satisfaction was comparable for all opioids except for sufentanil, which showed consistently lower patient satisfaction vs oxycodone. Similar results are reported by a parallel systematic review which also acknowledges similar limitations (Tan 2018 **Level I**, 8 RCTs, n=506) (6 RCTs overlap). In cancer pain management, oxycodone is comparable in efficacy and adverse effects to other strong opioids; very low-level evidence suggests lower risk of hallucinations with oxycodone vs morphine (Schmidt-Hansen 2018 **Level I** [Cochrane], 23 RCTs, n=2,144). With regard to adverse effects in the setting of cancer pain treatment, there were no differences between oxycodone vs other opioids except for less sleepiness with oxycodone vs morphine (Ma 2016a **Level I** [PRISMA], 11 RCTs, n=1,211) (5 RCTs overlap). In neuropathic pain, there is very low-quality evidence that oxycodone is effective in the treatment of painful diabetic neuropathy (4 RCTs, n=637) and postherpetic neuralgia (1 RCT, n=50) (Gaskell 2016b **Level I** [Cochrane], 5 RCTs, n=687).

Pethidine

Pethidine (meperidine) is a synthetic opioid with decreasing use worldwide due to multiple disadvantages compared to other opioids, and equally effective analgesic alternatives. Despite a common belief that it is the most effective opioid in the treatment of renal colic, it was no better than morphine (O'Connor 2000 **Level II**, n=103, JS 5) or hydromorphone (Jasani 1994 **Level II**, n=73, JS 4). Pethidine and morphine also had similar effects on the sphincter of Oddi and biliary tract and there was no evidence that pethidine was better in the treatment of biliary colic (Latta 2002 **NR**).

Pethidine induced more nausea and vomiting than morphine when used parenterally in the ED (Silverman 2004 **Level III-3**, n=193) and in the first 2 h after gynaecological surgery (Ezri 2002 **Level II**, n=200, JS4). Pethidine use postoperatively was associated with an increased risk of delirium in the postoperative period in comparison to other opioids (Swart 2017 **Level III-2 SR**, 3 studies [pethidine], n=877).

Accumulation of its active metabolite, norpethidine (normeperidine), is associated with neuroexcitatory effects that range from nervousness to tremors, twitches, multifocal myoclonus and seizures (Simopoulos 2002 **Level IV**, n=355). Impaired renal function increases the half-life of norpethidine; therefore, patients with poor renal function are at increased risk of norpethidine toxicity. Naloxone does not reverse and may increase the problems related to norpethidine toxicity.

Overall, the use of pethidine should be discouraged in favour of other opioids in adults (Latta 2002 **NR**) and in the paediatric setting (Benner 2011 **NR**).

Remifentanil

Remifentanil is an unusual opioid with a very fast onset of effect (<1 min) and an extremely short duration of action due to rapid metabolism by nonspecific esterases (Parashchanka 2014 **NR**). It is mainly used as a component of anaesthesia and carries a high risk of OIH; its use as an analgesic has primarily been studied in the setting of labour analgesia (Devabhakthuni 2013 **NR**) (see Section 9.1.3.1).

Sufentanil

Sufentanil (a derivative of fentanyl with rapid onset, short duration of action and no active metabolites) was originally used in the anaesthetic setting; its use has been introduced into the postoperative acute pain setting by the development of SL PCA (Frampton 2016 **NR**) (see Section 6.5.3).

4.3.1.3 | Atypical opioids

Buprenorphine

Buprenorphine is a semisynthetic derivative of thebaine, an alkaloid of opium and a potent, but *in vitro* partial, mu-opioid receptor agonist (Raffa 2014b **NR**) with high receptor affinity and slow dissociation from the mu-receptor and different downstream effects (G protein and adenylcyclase activation) than conventional opioids (Ehrlich 2019 **NR**; Davis 2012 **NR**; Pergolizzi 2010 **NR**). Furthermore, buprenorphine is a potent kappa-opioid receptor antagonist, a weak agonist at the nociceptin or opioid-receptor-like 1 (ORL-1) receptor and binds to the delta-opioid receptor. Buprenorphine, in particular the SL formulation, is increasingly used in the setting of acute pain management (Macintyre 2017 **NR**).

Buprenorphine shows biphasic pharmacokinetics with an initial distribution half-life of around 2–3 h and a terminal half-life of around 24 h; two-thirds of the medicine is excreted unchanged, mainly in faeces, while the remaining one-third is metabolised predominantly in the liver and gut wall via glucuronidation to an inactive metabolite, buprenorphine-3-glucuronide, and via CYP3A4 to norbuprenorphine, which has 40 times less analgesic effect than buprenorphine (Kress 2009 **NR**). However, in line with findings in animal experiments, an exploratory clinical investigation found respiratory depression more strongly associated with norbuprenorphine than with buprenorphine (Strang 2018 **EH PK**, n=11). Onset of effect is slower than for many other opioids; using experimental pain stimuli, the time to peak effect after administration of an IV bolus dose of buprenorphine was 70 to 90 min (Yassen 2006 **Level III-3 EH**).

The debate on buprenorphine being a partial or full mu-opioid receptor agonist in clinical practice continues (Holyoak 2019 **NR**) and is complicated by its multiple mechanisms of action. While *in-vitro* experiments have characterised buprenorphine as a partial agonist, clinically it behaves like a full mu-receptor agonist; in 23 of 24 studies identified in a systematic review, buprenorphine achieved analgesia comparable to full mu-opioid agonists (morphine, fentanyl, sufentanil and oxycodone) (Raffa 2014b **Level I**, 24 studies, n>1,270). The authors conclude that in clinically relevant doses, buprenorphine behaves like a full mu-opioid receptor agonist *in-vivo*. A subsequent systematic review found SL buprenorphine comparable to IM or IV morphine in acute pain management without any differences in pain control achieved, need for rescue analgesia or secondary outcomes (Vlok 2019 **Level I** [PRISMA], 9 RCTs, n=826) (3 RCTs overlap). This is confirmed in a paediatric population with IV buprenorphine vs IV morphine showing similar analgesic effects, but a longer duration of analgesia with buprenorphine (Murray 2018 **Level I**, 4 RCTs, n=193). An overarching meta-analysis of buprenorphine vs morphine by any route of administration in any population finds no difference in pain intensity at <1 h (WMD 0.18; 95%CI -0.45 to 0.81), conflicting evidence for other points of time (1 to 48 h) and no difference overall at all time points combined (WMD 0.29; 95%CI -0.62 to 0.03) (White 2018 **Level I** [PRISMA], 28 RCTs,

n=2,210) (all 9 RCTs overlap with Vlok 2019 and all 4 RCTs with Murray 2018). All other outcomes for analgesia and adverse effects (including respiratory depression) are not different except for less pruritus with buprenorphine (OR.0.31; 95%CI 0.12 to 0.84).

In animals as well as humans, in therapeutic doses there also appears to be no antagonism of other concurrently administered mu-agonist medicines and combined use should be effective (van Niel 2016 **NR**; Pergolizzi 2010 **NR**). In patients on opioid substitution therapy (OST) with daily SL buprenorphine (12 to 16 mg), high doses of IV hydromorphone (16 and 32 mg) and to a lesser extent IV buprenorphine (32 mg) achieved analgesic effects in an acute pain model (cold pressor test) (Huhn 2019 **Level II EH**, n=17, JS 4). In contrast, patients on OST with SL buprenorphine (2 to 22 mg/d) achieved no relief of experimental pain (cold pressor or electrical stimulation) with IV morphine (55 mg achieving plasma concentrations of 92 to 201 ng/mL), but reduced respiratory rates (Athanasos 2019 **Level II EH**, n=12, JS 2).

There is a ceiling effect for respiratory depression but not for analgesia in healthy volunteers (in the dose range tested of 200 to 400 mcg) (Dahan 2006 **Level III-2 EH**; Dahan 2005 **Level III-2 EH**). In clinical practice, transdermal (TD) buprenorphine has not been associated with any fatality in the National Poison Data System of the USA (Coplan 2017 **Level IV**, n=117 [TD burenorphine]). When used for OST, methadone use increased the risk of overdose death vs buprenorphine (RR 6.23; 95%CI 4.79 to 8.10) (Marteau 2015 **Level III-2**, n=2,418 [overdose deaths] in n=19,935,537 [prescriptions]). However, even with buprenorphine the overdose death rate was not zero, but 0.022/1000 prescriptions (vs 0.137/1000 prescriptions of methadone). In an analysis of overdose deaths, buprenorphine alone can cause fatal respiratory depression, although in most cases (90%) other medications, in particular benzodiazepines and other sedatives, were found (Selden 2012 **Level IV**, n=97). Similarly, in elderly opioid-naïve patients acute pain treatment with titration of SL buprenorphine (200 mcg steps with total doses of 200 to 3,000 mcg) resulted in cases of OIVI without a fatal outcome; all patients had risk factors such as advanced age, concurrent comorbidities, or the ingestion of other potential central nervous system depressants (Richards 2017 **Level IV**, n=6). A meta-analysis comparing buprenorphine with morphine finds no difference in the incidence of respiratory depression (defined as respiratory rate <8 to 12/min) (OR.2.07; 95%CI 0.78 to 5.51) or sedation (OR.1.44; 95%CI.0.76 to 2.74) (White 2018 **Level I** [PRISMA], 28 RCTs, n=2,210).

Should buprenorphine-induced respiratory depression occur, then complete reversal with naloxone is possible (Pergolizzi 2010 **NR**), although higher than usual doses and a longer duration infusion of naloxone are required (van Dorp 2006a **Level III-2 EH**; Yassen 2006 **Level III-3 EH**; Boom 2012 **NR**). This is confirmed in the case series referred to above, where naloxone bolus doses up to 2.2 mg and infusions for up to 20 h were used (Richards 2017 **Level IV**, n=6).

In animal models of pain, buprenorphine appears to have good efficacy for neuropathic pain (Hans 2007 **NR**). In the clinical setting, case reports have suggested that buprenorphine is effective in peripheral (Licina 2013 **Level IV**, n=4) and central neuropathic pain (Guetti 2011 **Level IV**). However, a specific effect cannot be supported or refuted based on current evidence (Wiffen 2015 **Level I** [Cochrane], 0 RCTs, n=0).

Buprenorphine may also have a reduced tendency to cause opioid-induced hyperalgesia (OIH) (Lee 2011 **NR**). In patients in opioid-substitution programs, buprenorphine reduced pain thresholds less than methadone (Compton 2001 **Level III-2 EH**, n=54). Using experimental pain stimuli in humans, buprenorphine, unlike conventional mu-opioid agonists, has been shown to be antihyperalgesic, which may be related in part to its kappa-opioid antagonist activity (Koppert 2005 **Level II EH**, n=15, JS 4). During major lung surgery under remifentanil infusion, perioperative buprenorphine infusion (25 mcg/h for 24 h) vs equianalgesic morphine infusion resulted in less hyperalgesia and allodynia around the incision and longer time until rescue analgesia requirements, with no long-term benefits at 3 mth (Mercieri 2017 **Level II**, n=64, JS 5).

However, in healthy volunteers, IV infusions of buprenorphine (0.3 mg) and morphine (10 and 20 mg) showed no differences in antihyperalgesic or analgesic effects; only IV buprenorphine (0.6 mg) enhanced the descending nociceptive inhibitory control (Ravn 2013 **Level II EH**, n=32, JS 5). Similarly, patients on OST with SL buprenorphine (2 to 22 mg/d) were hyperalgesic in the cold pressor test vs controls (buprenorphine 17±2 s vs control 34±6 s) (Athanasos 2019 **Level II EH**, n=12, JS 2).

Withdrawal symptoms, which may be seen if the medicine is ceased after long-term treatment, are milder and more delayed in onset (≥72 h) than other opioids (Kress 2009 **NR**). In a direct comparison of buprenorphine vs morphine withdrawal, withdrawal symptoms were far less with buprenorphine (subjectively and objectively) (Tompkins 2014 **Level III-1**, n=7). There is also less neonatal abstinence syndrome (NAS) in babies of mothers receiving buprenorphine vs methadone substitution (Jones 2012 **NR**). In the USA National Poison Data System, calls describing intentional abuse of an opioid were lower for TD buprenorphine than any conventional opioid; specifically, prescription adjusted rates for abuse were much higher for TD fentanyl vs TD buprenorphine (aRR 10.8; 95%CI 4.46 to 25.9) (Coplan 2017 **Level IV**, n= 2,687 [calls]).

Buprenorphine can be safely used in patients with renal impairment and has less immunosuppressive effect in animal experiments than pure mu-opioid agonists (Davis 2012 **NR**; Pergolizzi 2010 **NR**). However, buprenorphine has the potential to prolong the QT interval (Klivinyi 2018 **NR**). High doses of buprenorphine patch (above 40mcg/h) may cause QT wave prolongation that is reversible with a MOR antagonist; clinical significance of this is unclear (Merivirta 2015 **Level III-1**, n=110).

For use in OST and implications for perioperative management see Section 9.8.3.2

Tapentadol

Tapentadol is a combined mu-agonist and noradrenaline-reuptake inhibitor (Tzschentke 2014 **NR**). In contrast to tramadol, it has no relevant functional serotonin-reuptake inhibition and no active metabolites (Raffa 2012 **NR**). Therefore, serotonin syndrome with its use alone has not been reported in 2 systematic reviews (Channell 2018 **Level IV SR**, 13 RCTs & 3 studies & 8 CRs, n=21,995 [tapentadol-treated]; Gressler 2017 **Level IV SR**, 13 RCTs & 9 studies, n=12,138) (significant overlap). However, in spontaneous adverse drug event (ADE) reporting to the TGA, 16 cases consistent with serotonin syndrome were reported (14 with coadministration of serotonergic medications) (Abeyaratne 2018 **Level IV**, n=104 [reports for tapentadol]). A probable serotonin syndrome in the setting of tapentadol overdose in combination with amitriptyline and duloxetine has also been published (Walczyk 2016 **CR**). There is no effect on heart rate or blood pressure due to noradrenaline-reuptake inhibition in doses up to the maximum recommended 500 mg/d, even in patients with hypertension and/or on antihypertensives (Biondi 2014 **Level I**, 3 RCTs [*post hoc* analysis], n=1,464).

Elimination is by glucuronidation; severely impaired hepatic function may require dose adjustment (Xu 2010 **PK**).

Although in humans tapentadol has 18-fold lower affinity for the mu-receptor than morphine, it is only three times less potent as an analgesic due to its dual mechanism of action with synergy shown in site-specific administration studies (Christoph 2013 **BS**). With regard to tapentadol, the concept of "mu-load" (the % contribution of the opioid component to the adverse effect magnitude relative to a pure/classical mu-opioid at equianalgesic doses) has been discussed, suggesting that while conventional opioids have by definition a mu-load of 100%, atypical opioids have a mu-load <100%; for tapentadol using respiratory depression and constipation the mu-load is calculated ≤ 40% (Raffa 2018 **NR**).

The effect of tapentadol as a noradrenaline-uptake inhibitor on descending pathways of pain inhibition has been confirmed in diabetic neuropathy, where tapentadol use increased

conditioned pain modulation (Niesters 2014b **Level II**, n=24, JS 5). This mechanism of action suggests benefits in neuropathic pain (Vinik 2014 **Level II**, n=318, JS 5; Freo 2019 **NR**), but tapentadol also showed efficacy in nociceptive and inflammatory-pain models (Schiene 2011 **NR**) including postoperative pain (Lee 2014b **Level II**, n=352, JS 5) and cancer pain (Mercadante 2017 **Level IV SR**, 8 studies, n=792). In the setting of acute pain, tapentadol IR achieves similar analgesia to oxycodone IR, mostly in a 5:1 dose ratio, but with oxycodone resulting in an increased incidence of the gastrointestinal adverse effects nausea (OR 2.23; 95%CI 1.72 to 2.90), vomiting (OR 2.19; 95%CI 1.09 to 4.42) and constipation (OR 3.16; 95%CI 1.42 to 7.01) (each in 3 RCTs) (Hartrick 2010 **Level I**, 5 RCTs, n=2,831). A subsequent systematic review confirmed these results; tapentadol IR in doses of 50, 75 and 100 mg (with 75 mg being superior to 50 mg) provides similar analgesia to oxycodone IR 10 mg (Xiao 2017 **Level I** [PRISMA}, 9 RCTs, n=3,961) (4 RCTs overlap). The rate of nausea (RR 0.64; 95%CI 0.48 to 0.85), vomiting (RR 0.37; 95%CI 0.24 to 0.56) and constipation (RR 0.44; 95%CI 0.32 to 0.62) was lower with tapentadol IR 50 mg and nausea (RR 0.41; 95%CI 0.41 to 0.93) and constipation (RR 0.38; 95%CI 0.25 to 0.54) with 75 mg.

Data in the setting of a number of chronic pain conditions show similar or superior efficacy to conventional opioids with reduced rates of gastrointestinal adverse effects such as nausea, vomiting and constipation leading to reduced rates of treatment discontinuation (Riemsma 2011 **Level I**, 42 RCTs [8 RCTs tapentadol, n=6,698]). In a network meta-analysis of opioids for chronic pain treatment, tapentadol was identified as top-ranking due to low rates of overall adverse effects, in particular constipation, and lowest withdrawal rate for adverse effects (Meng 2017 **Level I** [PRISMA] [NMA], 32 RCTs, n unspecified).

Despite increasing use of this analgesic in many countries of the world (in particular the USA [approved 2008], Australia [2010] and Europe [2011]), only 4 (possibly 5 as double reporting of one case could not be excluded) single drug tapentadol overdose deaths could be identified (Channell 2018 **Level IV SR**, 13 RCTs, 3 studies & 8 CRs, n=21,995 [tapentadol treated]). Relative safety of tapentadol vs conventional opioids has been confirmed by data from the USA Researched Abuse, Diversion and Addiction-Related Surveillance (RADARS®) System Poison Center Program; there was no reported death due to tapentadol between 2010 and 2016 and it had the lowest rate of overdose deaths, major medical effects, serious adverse events and hospitalisations (data corrected for amounts dispensed) (Murphy 2018 **Level IV**, n=64,538 [reports]). Post-marketing surveillance by the manufacturer could also not identify any overdoses with fatal outcomes (Stollenwerk 2018 **Level IV**, n=10,758 [case reports]). In an experimental setting, tapentadol (100 mg) vs oxycodone (20 mg) (equianalgesic doses) had less respiratory depressant effects, but not 150 mg (van der Schrier 2017 **Level II EH**, n=18, JS 5).

Although a controlled medicine in all countries, tapentadol shows a lower rate of abuse and diversion than oxycodone and hydrocodone and a rate comparable to tramadol (Dart 2012 **Level IV**). Diversion rates of tapentadol in the USA (monitored by RADARS® - note that the SR preparation in the USA is tamper resistant) adjusted for amounts used were lower for tapentadol IR (0.03/1,000 prescriptions) and tapentadol SR (0.016) than all other scheduled oral opioids (0.172) (Dart 2016 **Level III-2**, n=38,388 [cases of diversion]). A subsequent analysis by the same system (adjusted for dosing units dispensed) confirms the lowest rate of diversion (comparable to tramadol) and lower, but not the lowest, rate of intentional abuse in reports to poison centres (tramadol and hydrocodone being lower) (Vosburg 2018 **Level III-3**, n multiple denominators). Rates of doctor shopping (sourcing from multiple providers) were higher for oxycodone vs tapentadol (OR 3.5; 95%CI 2.8 to 4.4) (Cepeda 2013b **Level III-2**) and rates of abuse lower for tapentadol vs oxycodone (OR 0.35; 95%CI 0.21 to 0.58) (Cepeda 2013a **Level III-2**).

Tramadol

Tramadol is commonly referred to as an atypical centrally acting analgesic because of its combined effects as an opioid agonist and a serotonin- and noradrenaline-reuptake inhibitor (Bravo 2017 **NR**; Raffa 2012 **NR**; Raffa 1992 **NR**). Although an effective analgesic, it may not provide adequate pain relief if used as the sole agent for the management of moderate to severe acute pain at the currently recommended doses (Thevenin 2008 **Level III-1**). However, compared to a variety of strong opioids (morphine, fentanyl, oxycodone, pethidine) when administered by PCA, tramadol had comparable analgesic efficacy (Murphy 2010 **Level I**, 12 RCTs, n=782). As discharge medication after surgery, the risk of prolonged tramadol use was similar, if not slightly higher than other short acting opioids (Thiels 2019 **Level III-2**, n= 444,764).

Limited low-quality evidence supports tramadol's analgesic effect in cancer pain, although it is not as effective as morphine in this indication (Wiffen 2017b **Level I** [Cochrane], 10 RCTs, n=958). Tramadol is an effective treatment for neuropathic pain with NNT of 4.4 (95%CI 2.9 to 8.8) (Duehmke 2017 **Level I** [Cochrane], 6 RCTs, n=438).

IV tramadol/IV morphine vs IV morphine has a minor opioid-sparing effect (WMD 6.9 mg; 95%CI 211.3 to 22.5), but does not reduce pain intensity (WMD -0.9/100; 95%CI -7.2 to 5.2) nor adverse effects (nausea, vomiting, sedation) (Martinez 2015 **Level I** [PRISMA], 14 RCTs, n=713).

The (+) enantiomer of tramadol is the stronger inhibitor of serotonin reuptake and the (-) enantiomer the more potent inhibitor of noradrenaline reuptake; tramadol is metabolised by CYP2D6 and the resultant active metabolite O-desmethyltramadol (M1) is a more potent mu-opioid receptor agonist than the parent drug (Lee 1993 **NR**). Patients who are poor metabolisers get less analgesic effect from tramadol (Stamer 2003 **Level III-2**), while ultrarapid metabolisers may be at increased risk of opioid-induced adverse effects including OIVI (Desmeules 1996 **Level II**, n=10, JS 3; Stamer 2008 **CR**). See also Section 1.7.3.2.

Coadministration with other medicines that inhibit CYP2D6 may also influence the effectiveness of tramadol. For example, pretreatment with paroxetine in healthy extensive metabolisers reduced the hypoalgesic effect of tramadol in an experimental pain model (Laugesen 2005 **Level II EH**, n=16 [4-way cross over], JS 5). Inhibition of $5HT_3$ receptors by ondansetron also decreased the analgesic effect of tramadol, as measured by increased tramadol requirements, in particular early after ondansetron administration (Stevens 2015 **Level I** [PRISMA] 6 RCTs, n=340), although this may also be a pharmacokinetic interaction (Hammonds 2003 **NR**). This has been confirmed in a subsequent RCT in hemithyroidectomy patients; here co-administration of IV tramadol (1.5 mg/kg) with ondansetron (0.1 mg/kg) vs tramadol alone reduced time to request for rescue analgesia (76.3 min vs 164.1) and analgesic efficacy at 0 to 60 min postoperatively (at 60 min: 2.51/10 (SD ± 0.66) vs 1.16/10 (± 0.68), but improved PONV scores (Murmu 2015 **Level II**, n=134, JS 4)

Tramadol's adverse-effect profile is different from other opioids. In the RADARS® System Poison Center Program, tramadol had the second-lowest rates of overdose deaths, major medical effects, serious adverse events and hospitalisations (data corrected for amounts dispensed) (Murphy 2018 **Level IV**, n=64,538 [reports]). The risk of respiratory depression is lower than with conventional opioids at equianalgesic doses (Mildh 1999 **Level II EH**, n=8 [cross over], JS 5; Tarkkila 1998 **Level II**, n=36, JS 4; Tarkkila 1997 **Level II**, n=36, JS 4) and it does not depress the hypoxic ventilatory response (Warren 2000 **Level II EH**, n=20 [cross over], JS 5). However, in a large series of tramadol overdoses in Iran, mainly due to deliberate self-harm or abuse, 3.6% experienced apnoea and required respiratory support or naloxone use (Hassanian-Moghaddam 2013 **Level IV**, n=525 [overdoses]). The mean time to presentation was 7.7 h (range 1 to 24 h); the mean dose causing apnoea was 2,125 mg (range 200 to 4,600 mg), significantly higher than in those not experiencing apnoea (1,383 mg; range 100 to 6,000 mg). One death in each group was reported. A further series of tramadol overdoses reported hypertension (38.4%), tachycardia (24.8%),

respiratory depression (20%) (median dose 2,750 mg), seizure (14.5%) and no serotonin toxicity (Habibollahi 2019 **Level IV**, n=359 [overdoses]). Similar findings are reported from the USA; respiratory depression with relatively higher doses than other symptoms (median dose 2,500 mg) and seizures, tachycardia, mild hypertension, but no serotonin toxicity (Ryan 2015 **Level IV**, n=71). Significant respiratory depression has also been described in a patient with severe renal failure, most likely due to accumulation of the metabolite M1 (Barnung 1997 **CR**).

There is a risk of inducing serotonin toxicity when tramadol is combined with other serotonergic medicines, in particular SSRIs (Nelson 2012 **Level IV SR**, 1 study & 9 CR, n=14). However, despite the widespread use of both medicines, there are only very few case reports (14 cases in above SR) on this interaction. The interaction might be complex, as SSRIs are often CYP2D6 inhibitors (eg sertraline, paroxetine and fluoxetine) and can thereby increase tramadol concentrations (Miotto 2017 **NR**). This might also mean that poor CYP2D6 metabolisers are at an increased risk of this interaction (Nelson 2012 **Level IV SR**, 1 study & 9 CR, n=14). Furthermore, administration of tramadol to elderly patients in the postoperative period was a risk factor for delirium (Swart 2017 **Level III-2 SR**, 1 study [tramadol]: Brouquet 2010 **Level IV**, n=133).

Tramadol has less effect on gastrointestinal motor function than morphine (Lim 2001 **Level II**, n=101, JS 5; Wilder-Smith 1999b **Level II**, n=62, JS 5; Wilder-Smith 1999a **Level II**, n=30, JS 5; Wilder-Smith 1997 **Level II**, n=10 [cross over], JS 5). Nausea and vomiting are the most common adverse effects and occur at rates similar to morphine (Lim 2001 **Level II**, n=101, JS 5; Radbruch 1996 **NR**), although an increased rate in comparison to a variety of strong opioids (morphine, fentanyl, oxycodone, pethidine) occurs with PCA use (OR 1.52; 95%CI 1.07 to 2.14) (Murphy 2010 **Level I**, 12 RCTs, n=782). The incidence of pruritus was reduced with tramadol (OR 0.43; 95%CI 0.19 to 0.98).

Tramadol did not increase the incidence of seizures compared with other analgesic agents in two observational studies (Gasse 2000 **Level III-2**, n=11,383; Jick 1998 **Level III-2**, n=10,916). Seizures were reported in tramadol intoxication, mainly due to deliberate self-harm or abuse, with recurrent seizures in 7 and 11.7% of patients (Hassanian-Moghaddam 2013 **Level IV**, n=525; Shadnia 2012 **Level IV**, n=100). Potential risk factors for seizure, other than overdose, were a history of traumatic brain injury, seizure activity secondary to hypoxia and use in combination with medications that lower seizure threshold (Miotto 2017 **NR**). Calls to the National Poison Data System of the American Association of Poison Control Centers were more likely to report seizures with tramadol vs tapentadol (RR 7.94; 95%CI 2.99 to 20.91) (Tsutaoka 2015 **Level III-2**, n=8,783 [calls]). The low rate of recurrence does not justify the prophylactic use of an anticonvulsant after an initial seizure (Shadnia 2012 **Level IV**, n=100).

An analysis of reports from United States Food and Drug Administration Adverse Event Reporting System showed an association between tramadol use and hypoglycaemia in comparison to all other opioids except methadone (Makunts 2019 **Level IV**, n=12,004,552).

Although withdrawal from tramadol is uncommon, abrupt cessation can lead to withdrawal symptoms, which can have features of classical opioid withdrawal or atypical withdrawal seen with SNRI antidepressants (similar to those described with venlafaxine withdrawal); gradual tapering is recommended and treatment with lorazepam and clonidine if necessary (Miotto 2017 **NR**).

Finally, tramadol has a lower abuse and misuse potential than conventional opioids, as reconfirmed by an expert committee on drug abuse of the German government (Radbruch 2013 **GL**); this is in line with previous findings and tramadol's status as a noncontrolled drug in most countries. However, in countries with low availability of conventional opioids, tramadol has a higher rate of abuse. This has been reported from China (Wang 2018b **Level III-2 SR**, 80 studies, n= 118,904) and Africa (Salm-Reifferscheidt 2018 **NR**): eg Egypt (Bassiony 2018 **Level IV**, n=1,135), Ghana (Fuseini 2019 **NR**) and Nigeria (Idowu 2018 **Level IV**, n=249). A detailed assessment of issues related to tramadol use and abuse internationally has been released by the WHO (WHO 2018 **NR**).

4.3.1.4 | Determinants of opioid dose

Interpatient opioid requirements vary greatly (Macintyre 1996 **Level IV**) and opioid doses therefore need to be titrated to suit each patient. Reasons for variation include patient age and gender, genetic differences and psychological factors as well as opioid tolerance.

Patient age

Age, rather than patient weight, appears to be a better determinant of the amount of opioid an adult is likely to require for effective management of acute pain. There is clinical and experimental evidence of a two-fold to four-fold decrease in opioid requirements as patient age increases (Gagliese 2008 **Level IV**, n=246; Coulbault 2006 **Level IV**, n=74; Gagliese 2000 **Level IV**, n=99; Macintyre 1996 **Level IV**, n=1,010; Burns 1989 **Level IV**, n=100). The decrease in opioid requirement is not associated with reports of increased pain (Macintyre 1996 **Level IV**, n=1,010; Burns 1989 **Level IV**, n=100).

This age-related decrease in opioid requirement appears mainly due to differences in pharmacodynamics or brain penetration rather than systemic pharmacokinetic factors (Minto 1997 **Level IV**, n=65; Scott 1987 **Level IV PK**; Macintyre 2008b **NR**). See also Section 9.2.3.

Sex-based differences

In general, females report more severe pain than males with similar disease processes or in response to experimental-pain stimuli (Hurley 2008 **NR**). This is more complicated than initially thought; in experimental-pain settings, women have lower pressure pain thresholds than men with no difference for cold and ischaemic pain (Racine 2012a **Level IV SR**, 122 studies, n unspecified). Temporal summation, allodynia and secondary hyperalgesia may be more pronounced in women than in men (Racine 2012b **Level IV SR**, 129 studies, n unspecified). In acute pain, there is more of a difference in pain perception than pain sensitivity (Ravn 2012 **Level IV EH**, n=100).

Evidence for differences of opioid responses in the acute pain setting varies. Across all studies in acute clinical pain with mu-opioids there is no association between sex and opioid response, however with PCA use there is greater analgesic effect in women (ES 0.22; 95%CI 0.02 to 0.42) (Niesters 2010 **Level I**, 25 RCTs, n unspecified). The effect is even more pronounced with morphine PCA (ES 0.36; 95%CI 0.17 to 0.56) and is similar in experimental-pain settings (ES 0.35; 95%CI 0.01 to 0.69). Likely explanations are interactions between oestrogen and opioid receptors (Lee 2013b **NR**). This is supported by preclinical data which show that hormones interact with the opioid system and that these interactions may produce meaningful sex-based differences in the subjective experience of opioids, but the direction of effect is variable and inconsistent (Huhn 2018 **BS SR**).

While response to opioids may differ, both the degree and direction of variation depend on many variables (Campesi 2012 **NR**; Dahan 2008a **NR**). This variation as well as other known and unknown factors involved in the very large interpatient differences in opioid requirements seen clinically, means that biological sex cannot be used as a basis for opioid-dose alteration and confirms the need to titrate doses to effect for each patient.

Genetics

Genetic variability may also affect a patient's response to opioids (see Section 1.7.3).

Psychological factors

The effect of psychological factors such as anxiety on opioid requirements is contradictory (see Section 1.2). Behavioural and psychological aspects associated with opioid tolerance and addiction are discussed in Sections 9.7 and 9.8.

Common opioid-related adverse effects are sedation, pruritus, nausea, vomiting, slowing of gastrointestinal function and urinary retention. A network meta-analysis has assessed frequencies for the various opioids at equianalgesic doses relative to morphine by PCA (Dinges 2019 **Level I** [NMA], 63 RCTs, n unspecified) (for more details see Section 6.3.2). Meta-analysis has also shown that the risk of adverse effects from opioids administered by PCA is similar to the risks from traditional methods of systemic opioid administration, with the exception of pruritus, which is increased in patients using PCA (Hudcova 2006 **Level I** [Cochrane] 55 RCTs, n=3,861).

However, there may be differences in the routine clinical setting (Dolin 2005 **Level IV SR**, 165 studies, n≈20,000; Cashman 2004 **Level IV SR**, 165 studies, n≈20,000). The following incidences (means) were associated with the use of PCA opioids: respiratory depression 1.2 to 11.5% (using decreased respiratory rate and oxygen desaturation, respectively, as indicators), nausea 32%, vomiting 20.7%, pruritus 13.8% and excessive sedation 5.3%. The incidences reported for IM opioid analgesia were: respiratory depression 0.8 to 37% (using the same indicators), nausea 17%, vomiting 21.9%, pruritus 3.4% and excessive sedation 5.2%.

Clinically meaningful opioid-related adverse effects are dose-related. There was an increased risk of 0.9% for nausea and 0.3% for vomiting for every 1 mg increase in PCA-morphine consumption after surgery (Marret 2005 **Level I**, 22 RCTs, n=2,307). In a prospective evaluation of elderly surgical inpatients (requiring a length of stay (LOS) >2 d and no PONV prophylaxis), increasing opioid dose also correlated directly with both nausea and vomiting incidence (Roberts 2005 **Level IV**, n=193). After laparoscopic cholecystectomy, once a threshold dose was reached (≈10 mg MED/d), every further 3–4 mg increase of MED/d was associated with one additional meaningful adverse effect or patient-day with such an event (Zhao 2004 **Level II**, n=193, JS 5).

Opioid-related adverse effects in surgical patients were associated with increased LOS in hospital and total hospital costs; the use of opioid-sparing techniques can be cost-effective (Oderda 2007 **Level III-2**; Barletta 2012 **NR**; Philip 2002 **NR**). Postsurgical patients who experienced an opioid-related adverse effect had a 55% longer LOS, 47% higher costs, 36% increased risk of readmission and 3.4 times higher risk of inpatient mortality (Kessler 2013 **Level III-2**, n=37,031). Similar results were found in the analysis of a large national hospital database (Oderda 2013 **Level III-2,** n=319,898). More specific information was reported subsequently where 10.6% of surgical patients experienced an opioid-related adverse event (Shafi 2018 **Level III-2**, n=135,379). Risk factors were higher opioid doses (MED 46.8 mg vs 30.0 mg) and opioid use for a longer duration (median 3.0 vs 2.0 d). Opioid-related adverse events were associated with increased inpatient mortality (OR 28.8; 95%CI 24.0 to 34.5 [2.9% increase in absolute mortality]), prolonged LOS (OR 3.1; 95%CI 2.8 to 3.4), high cost of hospitalisation (OR 2.7; 95% CI 2.4 to 3.0), higher rate of 30 d readmission (OR 1.3; 95%CI 1.2 to 1.4) and US$ 8,225 per event increase in cost. Similarly, in previously opioid-naïve patients receiving opioids after surgery, 9.1% experienced opioid-related adverse effects with an increased risk with prolonged IV administration and resulted in 29% higher costs of hospitalisation, 55% longer postoperative LOS, 29% lower odds of discharge home and 2.9 times the odds of death (Urman 2019 **Level III-2**, n= 12,218 [patients receiving opioids]).

Identifying patients at high risk of opioid-related adverse effects using clinical and demographic parameters is possible (Minkowitz 2014a **Level III-2**, n=6,285; Minkowitz 2014b **Level III-3**, n=3,697); identification of such high-risk patients enabled reduction of adverse effects and hospital costs.

Opioid-induced ventilatory impairment

OIVI is a more appropriate term to describe the effects of opioids on ventilation than respiratory depression alone (Macintyre 2011 **NR**). It encompasses the respiratory depression caused by

opioids (decreased central CO_2 responsiveness resulting in hypoventilation) and elevated partial pressure of CO_2 in arterial blood [$PaCO_2$]) (Boom 2012 **NR**) but also the depressed consciousness (decreased arousal and protection) and the subsequent upper airway obstruction (associated with lower airway motor tone) resulting from excessive opioid use. This combination is the most feared adverse effect of opioids, potentially with fatal consequences.

The most frequently reported risk factors for OIVI were older age, female gender, sleep-disordered breathing, obesity, renal impairment, pulmonary disease (in particular COPD), cardiac disease, diabetes, hypertension, neurologic disease, two or more comorbidities, opioid dependence, concomitant administration of sedatives, different routes of opioid administration and CYP450 enzyme polymorphisms, but patients without such risk factors can also develop OIVI (Gupta 2018b **Level IV SR**, 13 studies, n=871,912; Overdyk 2014 **Level IV**, n=134 [case reports]). Postoperative OIVI occurred in 5/1,000 cases with 85% in the first 24 h (95% CI 4.8 to 5.1) (Gupta 2018a **Level IV SR** [PRISMA], 12 studies, n=841,424). Increased risk is linked to cardiac disease (OR 1.7; 95%CI 1.2 to 2.5), pulmonary disease (OR 2.2; 95%CI 1.3 to 3.6), OSA (OR 1.4; 95%CI 1.2 to 1.7) and higher daily MED (24.7±14 mg vs 18.9±13.0 mg). Age, gender, BMI and ASA status are not identified as risk factors in this systematic review. In a closed claims study of postoperative OIVI, 88% of events occurred within 24 h postoperatively; risk factors included multiple prescribers (33%), concurrent administration of sedating medications (34%), and inadequate nursing assessments or response (31%) (Lee 2015b **Level IV**, n=92 [episodes of OIVI]). Other studies confirm that most postoperative events of OIVI occur in the first 24 h: within 24 h 88% (within 12 h 58%) (Weingarten 2015 **Level III-2**, n=134 [naloxone administrations]), 81% (34% within 6 h) (Ramachandran 2011 **Level IV**, n=33 [episodes of OIVI]) and 78% (57% within 12 h) (Taylor 2005 **Level III-2**, n=62 [episodes of OIVI]).

OIVI can usually be avoided by careful titration of the dose against effect and careful observation and monitoring. A variety of clinical indicators have been used to indicate OIVI caused by opioids; not all may be appropriate or sensitive.

A number of studies investigating hypoxia in the postoperative period in patients receiving opioids for pain relief have found that measurement of respiratory rate as an indicator of respiratory depression may be of limited value and that hypoxaemic episodes often occur in the absence of a low respiratory rate (Kluger 1992 **Level III-2**, n=40; Wheatley 1990 **Level III-2**, n=30; Catley 1985 **Level III-2**, n=32; Jones 1990 **NR**). As respiratory depression is almost always preceded by sedation, the best early clinical indicator is increasing sedation (Jungquist 2017 **NR**; Macintyre 2011 **NR**; Vila 2005 **NR**; Ready 1988 **NR**). This has also been acknowledged in recommendations of current guidelines (Jungquist 2020 **GL**; Chou 2016 **GL**).

Introduction of a numerical pain treatment algorithm in a cancer setting was followed by a review of opioid-related adverse effects (Vila 2005 **Level III-3**, n=25). Use of this algorithm, in which opioids were given to patients in order to achieve satisfactory pain scores, resulted in a two-fold increase in the risk of respiratory depression. Importantly, the authors noted that respiratory depression was usually not accompanied by a decrease in respiratory rate. Of the 29 patients who developed respiratory depression (either before or after the introduction of the algorithm), only 3 had a respiratory rate of <12 breaths/min but 27 (94%) had a documented decrease in their level of consciousness (Vila 2005 **Level III-3**, n=29). This study highlights the risk of titrating opioids to achieve a desirable pain score without appropriate patient monitoring.

In a review of PCA, case reports of respiratory depression in patients with obstructive sleep apnoea (OSA) were examined (Macintyre 2008a **NR**). It would appear that the development of respiratory depression might have been missed because of an apparent over-reliance on the use of respiratory rate as an indicator of respiratory depression; the significance of excessive sedation was not recognised.

In an audit of 700 acute pain patients who received PCA for postoperative pain relief, respiratory depression was defined as a respiratory rate of <10 breaths/min and/or a sedation score of 2 (defined as "asleep but easily roused") or more. Of the 13 patients (1.86%) reported with respiratory depression, 11 had sedation scores of at least 2 and, in contrast to the statements above, all had respiratory rates of <10 breaths/min (Shapiro 2005 **Level IV**, n=700). In a closed claims report, 62% of patients with postoperative OIVI (with 77% fatality or severe brain injury) experienced somnolence before the event (Lee 2015b **Level IV**, n=92 [events of OIVI]): the authors emphasise that assessment of sedation levels by nurses needs to be improved; 97% were judged preventable with better monitoring and response. These studies confirm that assessment of sedation is a more reliable way of detecting opioid-induced respiratory depression, although monitoring respiratory rate is still important.

Oxygen saturation levels may not be a reliable method of detecting respiratory depression in the postoperative setting. In addition to the use of supplemental oxygen delaying OIVI diagnosis, there may be reasons other than opioids for hypoxaemia. For example, when measurement of oxygen saturation was used as an indicator of respiratory depression, the incidence was reported to be 11.5% in patients receiving PCA and 37% in those given IM opioids (Cashman 2004 **Level IV SR**, 165 studies, n≈20,000). However, the same authors showed that patients given IM opioids reported more pain (moderate to severe pain in 67.2% and severe pain in 29.1% vs 35.8% and 10.4% respectively in PCA patients), suggesting that these patients received much lower doses of opioids (Dolin 2002 **Level IV SR**, 165 studies, n≈20,000). Continuous pulse oximetry (1 RCT, 3 studies) improves recognition of desaturations (<90%) (OR 15.7; 95% CI 10.6 to 23.2), with no effect on transfers to the ICU (RR 0.66; 95%CI 0.42 to 1.01) (Lam 2017 **Level IV SR** [PRISMA}, 2 RCTs & 7 studies, n>6,579).

Increases in $PaCO_2$ are the most reliable way of detecting respiratory depression. Continuous monitoring of transcutaneous CO_2 for 24 h after major abdominal surgery showed that patients given IV PCA morphine had higher CO_2 levels than those receiving epidural local anaesthetic/fentanyl infusions (McCormack 2008 **Level III-2**, n=30; Kopka 2007 **Level III-2**, n=28). Continuous capnography vs continuous pulse oximetry (1 RCT & 2 studies) identifies more events of respiratory depression (OR 5.83; 95%CI 3.54 to 9.63) (11.5% vs 2.8%) (Lam 2017 **Level IV SR** [PRISMA}, 2 RCTs & 7 studies, n>6,579).

Alternative monitors include continuous non-invasive respiratory-volume monitoring, which was described as identifying at-risk patients with a significant drop in minute ventilation or apnoeic/hypopnoeic episodes with high sensitivity (93%) and specificity (86%) (Voscopoulos 2014 **Level IV**, n=132).

Pharmacological strategies to reduce OIVI without affecting analgesia, eg by respiratory stimulants, have been investigated (Kimura 2014 **NR**; van der Schier 2014 **NR**).

Cardiac effects

The use of methadone has been linked to the development of prolonged QT interval with a risk of TdP and cardiac arrest (Alinejad 2015 **NR**; Mujtaba 2013 **NR**). Methadone has this effect due to inhibition of the cardiac-ion channel KCNH226 and the effect is dose-dependent. Most case reports of TdP in patients taking methadone have identified the presence of at least one other risk factor in addition to methadone (Justo 2006 **Level IV**, n=40 [TdP cases in 14 reports]; Fredheim 2008 **NR**). Risk factors include female sex, heart disease, other medicines with effects on the QT interval (eg tricyclic antidepressants [TCAs], antipsychotics, diuretics) or methadone metabolism, congenital or acquired prolonged QT syndromes, liver impairment and hypokalaemia (Mujtaba 2013 **NR**; Fredheim 2008 **NR**).

Of patients receiving substitution therapy of 60 to 100 mg/d methadone, 23% developed prolonged QT intervals during treatment vs none of the buprenorphine patients taking 16 to

32 mg 3 times/wk (Wedam 2007 **Level II**, n=165, JS 5). In the methadone group, the QT interval continued to increase over time, even with stable doses.

There is as yet no consensus regarding the benefits or otherwise of obtaining an electrocardiogram (ECG) in patients prior to starting methadone, although it may be that the threshold for doing so should be lower in patients with other concomitant risk factors, including those receiving higher doses of methadone (Cruciani 2008 **NR**). Overall, guidelines targeting the prevention of death from methadone can only offer weak recommendations due to lack of good data (Chou 2014 **GL**); a Cochrane review was unable to identify any studies suitable for inclusion (Pani 2013 **Level I** [Cochrane] 0 RCTs, n=0). No adverse cardiac events related to intraoperative methadone administration have been reported so far, although methadone (given along with other perioperative medications) has been associated with QT-prolongation in the post-operative period in over 50% of patients (Murphy 2019 **NR**).

The use of dextropropoxyphene also carries a risk of TdP (Barkin 2006 **NR**) (see above). Similarly, higher doses of oxycodone were linked to prolonged QT intervals (Fanoe 2009 **Level III-2**). Beside these opioids, buprenorphine and pethidine have also been associated with prolonged QT intervals (Klivinyi 2018 **NR**).

Nausea and vomiting

Nausea and vomiting are frequent adverse effects of opioid analgesia in a range of settings. PONV and its prevention have been studied the most extensively; hence the following discussion will focus on this data. PONV is common and related to opioid administration in a dose-dependent manner (Marret 2005 **Level I**, 22 RCTs, n=2,307; Roberts 2005 **Level IV**, n=193), although many other more relevant risk factors for PONV have also been identified (Apfel 2012 **Level IV SR**, 22 studies, n=95,154). Opioids are a risk factor for PONV (OR 1.39; 95%CI 1.20 to 1.60) but less so than female sex, history of previous PONV or motion sickness, inhalational anaesthesia and nonsmoking status. The biological mechanisms of PONV have not yet been completely unravelled (Horn 2014 **NR**).

Guidelines on the prevention and management of PONV have been published (Gan 2014 **GL**).

Medications used as components of multimodal analgesia and that are opioid-sparing may also reduce PONV. Opioid-sparing effect and PONV reduction occurs with concurrent administration of gabapentin (Grant 2016b **Level I** [PRISMA], 44 RCTs, n=3,489) and pregabalin (Grant 2016a **Level I** [PRISMA], 23 RCTs, n=1,693), nsNSAIDs (Maund 2011 **Level I**, 43 RCTs [PONV], n unspecified), ketamine (Assouline 2016 **Level I** [PRISMA], 19 RCTS, n=1,453) and lidocaine (Weibel 2018 **Level I** [Cochrane], 68 RCTs, n=4,525). See also sections covering these medications.

Opioid-sparing effect with no decrease in PONV is reported for paracetamol and coxibs (Maund 2011 **Level I**, 43 RCTs [PONV], n unspecified). However, paracetamol given IV preoperatively or intraoperatively reduces PONV; this effect is associated with improved analgesia, not reduced opioid requirements (Apfel 2013 **Level I** [PRISMA], 30 RCTs, n=2,364). Preoperative vs postoperative paracetamol reduces postoperative vomiting (RR 0.50; 95%CI 0.31 to 0.83) (Doleman 2015b **Level I** [PRISMA], 7 RCTs, n=544) (see also Section 4.1).

Antiemetic medications

Eight antiemetic medications effectively prevent PONV vs placebo: droperidol, metoclopramide, ondansetron, tropisetron, dolasetron, dexamethasone, cyclizine and granisetron (Carlisle 2006 **Level I** [Cochrane], 737 RCTs, n=103,237). The authors conclude that evidence for differences between the medications was unreliable due to publication bias. Despite limited data to compare adverse effects, droperidol was more sedative and headache more common after ondansetron.

Scientific fraud by Yoshitaka Fujii has influenced this meta-analysis on the efficacy of antiemetics, in particular the efficacy of granisetron and ramosetron is overestimated by inclusion of 168 fraudulent RCTs by his group (Carlisle 2012 **Level I**, 534 RCTs, n unspecified).

Ramosetron remains effective vs placebo (but less than reported previously) and maintains a statistical, but clinically questionable, advantage over ondansetron (Mihara 2013 **Level I**, 12 RCTs, n=1,372).

The efficacy of various single compounds in reducing incidence of PONV in the first 24 h has been confirmed in updated meta-analyses; dexamethasone 4–5 mg IV (NNT 3.7), 8–10 mg IV (NNT 3.8) (De Oliveira 2013b **Level I** [PRISMA], 60 RCTs, n=6,696); droperidol ≤1 mg IV (NNT 3.5 to 5 for high-risk patients) (Schaub 2012 **Level I**, 25 RCTs, n=2,957); metoclopramide 10 mg IV (NNT 7.8) (De Oliveira 2012b **Level I** [PRISMA], 30 RCTs, n=3,328); perphenazine (Schnabel 2010 **Level I**, 11 RCTs, n=2,081); $5HT_3$-antagonists ondansetron, granisetron, tropisetron and dolasetron (Tang 2012 **Level I**, 85 RCTs, n=15,269), palonosetron (Singh 2016a **Level I** [PRISMA], 22 RCTs, n unspecified) and TD hyoscine (scopolamine) (Apfel 2010 **Level I**, 25 RCTs, n=3,298). All 5-HT_3 antagonists are superior to placebo in reducing incidence of PONV (125 RCTs, n=16,667 patients) (Tricco 2015a **Level I** [NMA], 450 RCTs, n=80,410).

NK1 receptor antagonists are also used in treatment and prophylaxis of PONV (George 2010 **NR**). Aprepitant (80 mg) reduces the incidence of nausea vs placebo (pooled RR 0.60; 95%CI 0.47 to 0.75) (3 RCTs, n=224) and vomiting (pooled RR 0.13; 95%CI 0.04 to 0.37) (3 RCTs, n=224) (Liu 2015 **Level I** [PRISMA], 14 RCTs, n=4,322). However, neither 40 mg (3 RCTs, n=1,171) nor 125 mg (2 RCTs, n=1,085) are superior to ondansetron 4 mg. After craniotomy, IV fosaprepitant 150 mg was significantly more effective than IV ondansetron 4 mg (6 vs 50% vomiting) (Tsutsumi 2014 **Level II**, n=64, JS 5) and more effective than IV droperidol 1.25 mg (Atsuta 2017 **Level II**, n=200, JS 5).

Propofol (1 mg/kg) close to the end of surgery reduced PONV significantly vs placebo (Kim 2014a **Level II**, n=107, JS 4). Caffeine 500 mg IV was ineffective in preventing PONV and increased rates of nausea (Steinbrook 2013 **Level II**, n=136, JS 3).

Combinations of antiemetics may be more effective than one medication given alone. Prophylaxis with the combination of a $5HT_3$-receptor antagonist and dexamethasone was associated with lower use of rescue antiemetics than $5HT_3$-receptor antagonist or dexamethasone alone (Tricco 2015a **Level I** [NMA], 450 RCTs, n=80,410; Kovac 2006 **Level I**, 49 RCTs, n=12,752), also after strabismus surgery in children (Shen 2014 **Level I**, 13 RCTs, n=2,006). Similarly, the combination of droperidol and ondansetron was additive (Chan 2006 **Level II**, n=400, JS 5). Other combinations that were more effective than either medicine given alone were cyclizine/granisetron (Johns 2006 **Level II**, n=960, JS 5), dexamethasone/haloperidol (Chu 2008 **Level II**, n=400, JS 5) and dexamethasone/dolasetron (Rusch 2007 **Level II**, n=242, JS 5). The addition of metoclopramide to dexamethasone also led to better PONV prophylaxis but, compared with dexamethasone 8 mg alone, only if doses of 25 mg and 50 mg metoclopramide were used, not 10 mg (Wallenborn 2006 **Level II**, n=3,140, JS 4). Oral aprepitant 80 mg added to ondansetron reduced the rate of postoperative vomiting in bariatric surgery patients for 72 h (Sinha 2014 **Level II**, n=125, JS 5).

Droperidol and, to a lesser extent, ondansetron may lead to prolonged QT intervals. Concerns about the potential for serious cardiac arrhythmias secondary to QT prolongation associated with droperidol led to a "black box" warning by the USA FDA in 2001. Following this there has been a significant reduction in the use of this medication, even though the warning was felt by many to be unwarranted (Habib 2008b **NR**). Mild QT prolongation can occur with anaesthesia and surgery. Saline administration vs 0.625 and 1.25 mg IV droperidol were associated with similar QT prolongation in the postoperative period (White 2005 **Level II**, n=120, JS 5). Similarly, 1.25 mg droperidol did not prolong QT interval (Toyoda 2013 **Level II**, n=72, JS 3). A large review of surgical patients in the periods 3 y before (n=139,932) and 3 y after (n=151,256) the FDA black box warning merged anaesthesia database information with information from ECG and other databases as well as patients' case notes, and recorded all patients who had documented prolonged QT

intervals, TdP or death within 48 h of their surgery (Nuttall 2007 **Level III-3**). Despite a reduction in droperidol use from 12 to 0% of patients following the warning, there was no difference in the incidence of QT prolongation, ventricular tachycardia, or death within 48 h of surgery and no clearly identified case of TdP related to use of droperidol. The authors concluded that for low-dose droperidol, the "black box" warning was "*excessive and unnecessary*". The scientific basis of the decision in favour of a "black box" warning has been questioned as a range of data show that the incidence of QT prolongation and TdP development is similar for low-dose droperidol and other compounds used to treat PONV (Halloran 2010 **NR**). The authors of guidelines for the management of PONV also express concerns about the FDA caution and state "*due to the 2001 black box warning, droperidol is not the first choice for PONV prophylaxis in many countries*" (Gan 2014 **GL**).

Haloperidol has also been associated with QT prolongation and TdP (Habib 2008a **NR**). Using data from studies published up until 1988, a meta-analysis showed that haloperidol is also an effective antiemetic (Buttner 2004 **Level I**, 23 RCTs, n=1,468). Subsequent studies have confirmed its effectiveness vs placebo (Aouad 2007 **Level II**, n=93, JS 4), ondansetron (no differences in efficacy, adverse effects or QT intervals) (Rosow 2008 **Level II**, n=244, JS 2; Aouad 2007 **Level II**, n=93, JS 4; Lee 2007 **Level II**, n=90, JS 5) and droperidol (equally effective) (Wang 2008 **Level II**, n=150, JS 5). Haloperidol/ondansetron was more effective than ondansetron alone (Grecu 2008 **Level II**, n=268, JS 3) and haloperidol/dexamethasone was also more effective than either medication given alone (Wang 2012 **Level II**, n=135, JS 3; Chu 2008 **Level II**, n=400, JS 5), again with no difference in adverse effects or QT intervals. Compared with droperidol, the only advantage of haloperidol may be "*that there is no black box warning*" (Ludwin 2008 **NR**).

Dolasetron (IV and oral formulations) is contraindicated by the Canadian authorities for any therapeutic use in children and adolescents aged <18 y and the prevention or treatment of PONV in adults because of the risk of QT prolongation (Health Canada 2006 **GL**). This age restriction is not limited to Canada but applies in a number of other countries including the UK. The effect of therapeutic doses of dolasetron (and ondansetron) on QT prolongation is, however, minimal (6% from baseline) (n=1,429) (Obal 2014 **Level III-3**, n=1,429); a case of prolonged QT interval has been reported after overdose (Rochford 2007 **CR**). More patients receiving granisetron/dexamethasone experience an arrhythmia vs placebo (OR 2.96; 95 %CI 1.11 to 7.94), ondansetron (OR 3.23; 95 %CI 1.17 to 8.95), dolasetron (OR 4.37; 95% CI 1.51 to 12.62), tropisetron (OR 3.27; 95 %CI 1.02 to 10.43), and ondansetron/dexamethasone (OR 5.75; 95% CI 1.71-19.34) (Tricco 2015b **Level I** [NMA], 31 RCTs, n=6,623).

Other antiemetic interventions

Low-dose naloxone (≤ 1 mcg/kg/h) reduces opioid-related postoperative nausea (RR 0.80; 95%CI 0.67 to 0.95), but has no effect on vomiting (RR 0.83; 95%CI 0.63 to 1.09) (Barrons 2017 **Level I** [PRISMA], 9 RCTs, n=946).

Mirtazapine vs placebo reduces PONV (RR 0.44; 95%CI 0.32 to 0.62) (3 RCTs) and has similar effects to ondansetron (1 RCT), while it also reduces anxiety (Bhattacharjee 2019 **Level I** [PRISMA], 7 RCTs, n=581).

Supplemental IV crystalloid infusions reduce the risk of PONV and the need for rescue antiemetics (Jewer 2019 **Level I** [Cochrane], 41 RCTs, n=4,424). IV dextrose perioperatively vs control does not reduce the risk of PONV, but does reduce the need for rescue antiemetics (Kim 2018 **Level I** [PRISMA], 7 RCTs, n=701).

Supplemental oxygen (FiO_2 80%) in the postoperative period does not reduce PONV (Orhan-Sungur 2008 **Level I**, 10 RCTs, n=1,729), but high inspired oxygen concentrations intraoperatively reduce PONV in patients receiving inhalational anaesthetics without prophylactic antiemetics (Hovaguimian 2013 **Level I**, 22 RCTs, n=7,001).

PC6 acupoint stimulation (by any means: acupuncture, electro-acupuncture, transcutaneous electrical acupoint stimulation, transcutaneous nerve stimulation, laser stimulation, capsicum plaster, acu-stimulation device and acupressure) reduces the incidence of nausea (RR 0.68; 95%CI 0.60 to 0.77) (40 RCTs, n=4,742), vomiting (RR 0.60; 95%CI 0.51 to 0.71) (45 RCTs, n=5,147) and rescue antiemetic requirements (RR 0.64; 95%CI 0.55 to 0.73) (39 RCTs, n=4,622) based on low quality evidence (Lee 2015a **Level I** [Cochrane], 59 RCTs, n=7,667). PC6 acupoint stimulation vs antiemetics (metoclopramide, cyclizine, prochlorperazine, droperidol, ondansetron and dexamethasone) is similarly effective on all three above outcomes. Acupuncture/acupressure is the only nonpharmacological intervention included in the PONV management guideline developed by the Society for Ambulatory Anesthesiology, endorsed by ANZCA (Gan 2014 **GL**).

Ginger (*Zingiber officinale*) reduces the severity (SMD −0.25; 95%CI −0.46 to −0.04), but not the incidence of PONV (Toth 2018 **Level I** [PRISMA], 10 RCTs, n=918).

Aromatherapy vs placebo has no effect on incidence of PONV, but may reduce need for rescue antiemetic requirements; both statements are based on low-quality evidence (Hines 2018 **Level III-1 SR** [Cochrane], 16 RCTs and CCTs, n=1,036).

In a pilot RCT, chewing gum was not inferior to ondansetron 4 mg for PONV treatment after laparoscopic or breast surgery in females (Darvall 2017 **Level II**, n=94, JS 3).

Impairment of gastrointestinal motility

Opioids are well described as inducing constipation with chronic use (Ahmedzai 2006 **NR**). Opioids impair return of bowel function after surgery (Barletta 2012 **NR**). A daily dose of hydromorphone IV >2 mg was the most obvious risk factor for postoperative ileus (Barletta 2011 **Level IV**, n=279). Another risk factors was longer IV opioid use and postoperative ileus was a risk factor for prolonged hospital LOS. After laparotomy and laparoscopic cholecystectomy and colectomy, patients with postoperative ileus received higher opioid doses (median MED 285 mg vs 95 mg); in postoperative patients with an ileus, opioid doses above the median were associated with increased LOS (3.8 d to 7.1 d), total costs (US$ 8,458 to 19,562), and readmission after laparoscopic surgeries (4.8% to 5.2%) (Gan 2015 **Level III-3**, n= 138,068).

Overall, treatment of opioid-induced constipation due to chronic intake with opioid antagonists (methylnaltrexone, naloxone, naloxegol, alvimopan, axelopran, or naldemedine) (NNT 3.4 to 7) (23 RCTs) is more effective than laxatives (lubiprostone [NNT 15] or prucalopride) (4 RCTs) (Nee 2018 **Level I** [PRISMA], 27 RCTs, n=8,881); the effects of the various opioid antagonists are similar, while the two laxatives are only slightly better than placebo. A network meta-analysis identified SC methylnaltrexone as the most effective opioid antagonist to treat opioid-induced constipation (Sridharan 2018 **Level I** [NMA], 23 RCTs, n unspecified) (17 RCTs overlap).

The peripheral-acting opioid antagonists alvimopan and methylnaltrexone are effective in reversing opioid-induced slowing of gastrointestinal transit time and constipation and alvimopan is an effective treatment for postoperative ileus (McNicol 2008 **Level I** [QUOROM], 22 RCTs, n=2,358) (4 RCTs overlap with Nee 2018); insufficient evidence exists about the efficacy or safety of naloxone or nalbuphine. The efficacy of alvimopan has been confirmed in subsequent studies summarised in a review (Kraft 2010 **NR**). After radical cystectomy in an RCT not included in any of the above systematic reviews, alvimopan resulted in faster gastrointestinal recovery, shorter hospital LOS and reduced incidence of postoperative ileus (7 vs 26%) with reduced resulting morbidity (8.4 vs 29.1%) without increased adverse effects (Lee 2014a **Level II**, n=280, JS 3).

A combined formulation of controlled-release (CR) oxycodone and naloxone is available in many jurisdictions. Compared with CR oxycodone alone in patients with chronic non-cancer pain, the combination formulation resulted in similar analgesic efficacy but less bowel dysfunction (Lowenstein 2010 **Level II** [pooled analysis of 2 RCTs], n=578, JS 5). It has been suggested that these benefits were transferable to acute pain settings (Kuusniemi 2012 **NR**). This was not confirmed

after laparoscopic hysterectomy where oxycodone/naloxone CR had no beneficial effect on constipation or other opioid adverse effects vs oxycodone CR (Comelon 2013 **Level II**, n=85, JS 5). IV administration of the crushed combination resulted in reduced drug liking and other subjective effects (Colucci 2014 **Level II EH**, n=24, JS 3).

Urinary retention

Opioids cause urinary retention due to presumed central and peripheral mechanisms. Opioid antagonists reverse this effect; naloxone reversed opioid-induced urinary retention in 100% of patients, while the peripheral opioid antagonist methylnaltrexone IV was effective in 42% of study participants (Rosow 2007 **Level III-1 EH**, n=13). These data suggest that at least part of the bladder dysfunction caused by opioids is peripherally mediated.

Premedication with gabapentin reduces urinary retention caused by opioids (NNT 7) (Tiippana 2007 **Level I** [QUOROM], 22 RCTs, n=1,909). This effect is most likely related to the opioid-sparing effect of gabapentin.

Pruritus

The mechanism of opioid-induced pruritus, which is particularly common after neuraxial opioid administration, is not fully understood but central mu-opioid receptor-mediated mechanisms are thought to be the primary cause (Ganesh 2007 **NR**). However, a serotonergic mechanism has also been suggested (Aly 2018 **Level II,** n=40, JS 4) (see also Section 4.3.1.5).

Naloxone, naltrexone, nalbuphine and droperidol are effective in the treatment of opioid-induced pruritus, although minimum effective doses remain unknown (Kjellberg 2001 **Level I**, 22 RCTs, n=1,477 patients); doses >2 mcg/kg/h of naloxone are more likely to lead to reversal of analgesic effects. Low-dose continuous naloxone (0.25–1 mcg/kg/h) has the best evidence (Miller 2011 **NR**). Nalbuphine specifically is more effective than placebo (3 RCTs), control (3 RCTs) and diphenhydramine (1 RCT) in reducing pruritus (Jannuzzi 2016 **Level I**, 9 RCTs, n=1,128). Furthermore, ondansetron reduces the incidence of opioid-induced pruritus after neuraxial administration only in non-obstetric patients (RR 0.63; 95%CI 0.45 to 0.89) (3 RCTs, n=235) and not in obstetric patients (RR 0.84; 95%CI 0.69 to 1.03) (7 RCTs, n=576) (Wang 2017b **Level I** [PRISMA], 10 RCTs, n=811).

Cognitive function and confusion

While opioids can be the cause of cognitive dysfunction, confusion and delirium, it is surprising that, after cardiac surgery, IM morphine 5 mg was superior to IM haloperidol 5 mg in treating delirium (Atalan 2013 **Level II**, n=53, JS 2). This suggests that undertreated pain is a relevant consideration. Similarly, in elderly patients after hip fracture repair, opioids were not an important predictor of postoperative delirium (Sieber 2011 **Level IV**, n=236).

The risk of delirium and/or changes in cognitive function has been compared in patients receiving different PCA opioids. There was no statistically significant difference in the rates of confusion between morphine and fentanyl (14.3 vs 14.3%) but there was less depression of cognitive function with fentanyl (Herrick 1996 **Level II**, n=96, JS 2). No differences in cognitive function were reported in patients receiving tramadol vs morphine (Silvasti 2000 **Level II**, n=60, JS 4) or fentanyl (Ng 2006 **Level II**, n=30, JS 5) but cognition has been found to be poorer with hydromorphone vs morphine (Rapp 1996 **Level II**, n=61, JS 4).

Pethidine use postoperatively was associated with an increased risk of delirium in the postoperative period in comparison to other opioids (Swart 2017 **Level III-2 SR**, 3 studies [pethidine], n=877). Tramadol has been identified as a risk factor for postoperative delirium in the elderly following abdominal surgery (Swart 2017 **Level III-2 SR**, 1 study [tramadol]: Brouquet 2010 **Level III-2**, n=118).

Tolerance and hyperalgesia

In the absence of disease progression, a decrease in the effectiveness of opioid analgesia has traditionally been attributed to opioid tolerance. It is now known that administration of opioids can lead to both opioid-tolerance (a desensitisation of antinociceptive pathways to opioids) and, paradoxically, to opioid induced hyperalgesia (OIH: a sensitisation of pronociceptive pathways leading to pain hypersensitivity) and that both these phenomena can significantly reduce the analgesic effect of opioids (Mao 2015 **NR**; Low 2012 **NR**; Lee 2011 **NR**). The mechanisms underlying the development of tolerance and OIH are still not fully understood but, as with neuropathic pain, are thought to include activation of the glutaminergic system via the NMDA receptor, GABA receptors and possibly the innate neuroimmune system (Arout 2015 **BS NR**) as well as peripheral mu-opioid receptors (Weber 2017 **NR**).

It may be useful here to distinguish "pharmacological tolerance" (ie tolerance, as defined in Section 9.7.1 "the predictable and physiological decrease in the effect of a drug over time") and "apparent tolerance", where both tolerance and OIH contribute to a decrease in the effectiveness of opioids (Chang 2007 **NR**; Mao 2008 **NR**). The clinical significance of this mix, and the relevant contribution of pharmacological tolerance and OIH to apparent tolerance in any particular patient is difficult, if not impossible, to determine (Low 2012 **NR**). However, inadequate pain relief because of pharmacological tolerance may improve with opioid dose escalation, while improvements in analgesia in the presence of OIH may follow a reduction in opioid dose (Mao 2008 **NR**; Chu 2008 **NR**; Chang 2007 **NR**).

A formal diagnosis of hyperalgesia may require quantitative sensory testing (QST), that is, serial assessment of the responses to varying intensities of a nociceptive stimulus, in order to determine pain thresholds (Mitra 2008 **NR**). QST before and after starting chronic opioid therapy may assist in the differentiation between OIH and pharmacological tolerance (Chu 2008 **NR**) but this is unlikely to become common practice in the acute pain setting. OIH is identified by reduced pain tolerance to noxious thermal (hot and cold) stimuli, but not electrical stimuli, in patients with chronic opioid exposure for pain management and for opioid use disorder treatment (here more evident) (Higgins 2019 **Level III-3 EH SR** [PRISMA], 26 studies, n=2,706); pain detection thresholds remain unchanged. However, an attempt to identify a QST method to detect hyperalgesia in chronic pain patients on long-term opioids failed, as none of the measures could be used as a definitive standard (Katz 2015 **Level IV EH SR**, 14 studies, n unspecified). The pain types investigated include cold, heat, pressure, electrical, ischaemic and injection; only heat pain sensitivity showed promise.

Studies of OIH are confounded by factors such as pain modality tested, route of administration and type of opioid (Weber 2017 **NR**). Psychological factors such as pain-related distress and catastrophising might also affect pain sensitivity in those taking opioids for chronic pain (Edwards 2011 **Level III-2**, n=276; Eyler 2013 **NR**). Illicit substance use, affective characteristics, or coping styles may also play a role here (Higgins 2019 **Level III-3 EH SR** [PRISMA], 26 studies, n=2,706). Additionally, increasing opioid dose will worsen OIH (Colvin 2019 **NR**). Practical clinical challenges include lack of consensus on "the" diagnostic test, and overlap with tolerance, drug withdrawal and neuropathic pain.

It is probable that the degree of OIH varies between opioids. Remifentanil in particular (Fletcher 2014 **Level I** [PRISMA], 27 RCTs, n=1,494; Kim 2014b **Level IV EH SR**, number of studies unspecified, n unspecified; Rivosecchi 2014 **Level IV SR**, 35 studies, n unspecified) (significant overlap between all three SRs), but also morphine, in high doses, may be more likely to result in OIH than some other opioids; experimental data and a very limited number of case reports have shown an improvement when morphine doses were reduced or a change to methadone, fentanyl or sufentanil was made (Angst 2006 **NR**). Similarly, it appears that opioids differ in their ability to induce tolerance. Medications such as methadone, fentanyl and sufentanil promote receptor internalisation and thereby receptor

recycling; in contrast, the activation of opioid receptors by morphine leads to little or no receptor internalisation and thereby increased risk of development of tolerance (Joo 2007 **NR**). The difference between opioids is one reason why opioid-rotation may be a useful strategy in the clinical setting in attempts to improve pain relief (see Section 9.7.6.4).

In the setting of postoperative pain, high intraoperative doses of opioids resulted in higher postoperative pain intensity than controls at 1 h (MD 9.4/100; 95%CI 4.4 to 14.5), 4 h (MD 7.1/100; 95%CI 2.8 to 11.3) and 24 h (MD 3/100; 95%CI 0.4 to 5.6) and higher postoperative morphine use over 24 h (SMD 0.7; 95%CI 0.37 to 1.02) (Fletcher 2014 **Level I** [PRISMA], 27 RCTs, n=1,494). These results are mainly influenced by remifentanil due to limited data with other opioids. Overall, the effect of remifentanil is dose dependent (Angst 2015 **NR**).

Compared with abrupt cessation, gradual withdrawal from a target concentration 2.5 ng/mL of a remifentanil infusion for 30 min (by 0.6 ng/mL target concentration every 5 min) induced no OIH (pain similar to placebo) measured with the heat pain test, but not the cold pressor test (Comelon 2016 **Level II EH**, n=19, JS 5). This was confirmed in a clinical setting of thyroidectomy, where gradual tapering of a remifentanil infusion (from 0.3 to 0.1 mcg/kg/min over at least 30 min) reduced postoperative pain at 1 and 2 h and rescue analgesia requirements (Han 2015 **Level II**, n=62, JS 5).

NMDA-receptor antagonists (mainly ketamine [8 RCTs] but also magnesium [5 RCTs] and amantadine [1 RCT]) reduce the development of acute tolerance/OIH associated with remifentanil use (Wu 2015 **Level I** [QUOROM], 14 RCTs, n=729). Attentuation occurs with pregabalin (Lee 2013a **Level II**, n=93, JS 5; Jo 2011 **Level II**, n=60, JS 5), propofol (subgroup analysis: 6 RCTs, n=341) (Fletcher 2014 **Level I** [PRISMA], 27 RCTs, n=1,494) and N_2O (Wehrfritz 2016 **Level II EH**, n=21, JS 5; Echevarria 2011 **Level II**, n=50, JS 4). Low-dose naloxone (0.25 mcg/kg/h intraoperatively) also reduced postoperative opioid requirements when combined with high dose remifentanil (and improved time to bowel recovery) (Xiao 2015 **Level II**, n=75, JS 5). In an experimental setting, propranolol infusion reduced the size of area of secondary hyperalgesia induced by remifentanil to being not significantly different from baseline (Chu 2012 **Level II EH**, n=10 [cross over], JS 4). In animal experiments, the effects of gabapentin and ketamine on fentanyl-induced hyperalgesia were supra-additive (Van Elstraete 2011 **BS**).

The challenge faced by the health professional is that if inadequate pain relief is due to OIH, a reduction in opioid dose may help; if it is due to opioid tolerance, increased doses may provide better pain relief (Colvin 2019 **NR**; Huxtable 2011 **NR**; Mao 2008 **NR**). There are case reports of patients with cancer and chronic noncancer pain taking high doses of opioid who developed OIH and whose pain relief improved following reduction of their opioid dose (Chang 2007 **CR**; Angst 2006 **CR**); there are no data in the acute pain setting.

When a patient who has been taking opioids for a while (either legally prescribed or illicitly obtained) has new and ongoing tissue injury with resultant acute pain, a reasonable initial response to inadequate opioid analgesia, after an evaluation of the patient and in the absence of evidence to the contrary, is a trial of higher opioid doses (Huxtable 2011 **NR**; Chang 2007 **NR**). If the pain improves, this would suggest that the inadequate analgesia resulted from tolerance; if pain worsens, or fails to respond to dose escalation, it could be a result of OIH (Chang 2007 **NR**). Fortunately, some of the strategies that may be tried in an attempt to attenuate opioid tolerance in the acute pain setting may also moderate OIH (see below).

Other reasons for increased pain and/or increased opioid requirements should also be considered. These include acute neuropathic pain, pain due to other causes including postoperative complications, major psychological distress and aberrant drug-seeking behaviours (see Sections 9.7 and 9.8) (Edwards 2011 **Level III-2**; Macintyre 2015 **NR**; Gourlay 2008 **NR**).

The clinical relevance of the phenomena of opioid tolerance and OIH in the setting of perioperative analgesia remains under discussion (Colvin 2019 **NR**) (See also Section 9.7.2 and 9.8.1).

Tolerance to adverse effects of opioids

Tolerance to the adverse effects of opioids also occurs; tolerance to sedation, cognitive effects, nausea and respiratory depression can occur reasonably rapidly but there is little, if any, change in miosis or constipation (Chang 2007 **NR**).

KEY MESSAGES

1. Dextropropoxyphene has low analgesic efficacy (**U**) (**Level I** [Cochrane Review]).
2. Tramadol is an effective treatment for neuropathic pain (**S**) (**Level I** [Cochrane Review]).
3. Droperidol, metoclopramide, ondansetron, tropisetron, dolasetron, dexamethasone, cyclizine, granisetron (**U**) (**Level I** [Cochrane Review]), supplemental crystalloid infusions (**N**) (**Level I** [Cochrane Review]), palonosetron and mirtazapine (**N**) (**Level I** [PRISMA]) are effective in the prevention of postoperative nausea and vomiting.
4. PC6 acupoint stimulation by multiple techniques reduces postoperative nausea and vomiting (**S**) (**Level I** [Cochrane Review]).
5. Neurokinin-1 receptor antagonists aprepitant (**S**) (**Level I** [PRISMA]) and fosaprepitant (**U**) (**Level II**) are effective in the prevention of postoperative nausea and vomiting.
6. Intraoperative administration of the long acting opioid methadone reduces consumption of shorter acting opioids in the 24 hours after surgery (**N**) (**Level I** [PRISMA]). Safety data suggest an increased risk of opioid induced ventilatory impairment due to the long and unpredictable half-life of methadone (**N**) (**Level IV**).
7. Opioids in high doses, in particular remifentanil, can induce hyperalgesia and/or acute tolerance (**S**) (**Level I** [PRISMA]).
8. Propofol (**U**) (**Level I** [PRISMA]), NMDA-receptor antagonists (**U**) (**Level I** [QUOROM]), pregabalin (**U**) (**Level II**), nitrous oxide (**N**) (**Level II**) and gradual tapering of remifentanil dose (**N**) (**Level II**) attenuate acute tolerance and/or hyperalgesia induced by remifentanil.
9. NSAIDs, gabapentin, pregabalin, systemic lidocaine and ketamine are opioid-sparing medications and reduce opioid-related adverse effects (**S**) (**Level I** [PRISMA]).
10. Paracetamol given preoperatively and intraoperatively reduces postoperative nausea and vomiting; this effect is associated with improved analgesia, not reduced opioid requirements (**S**) (**Level I** [PRISMA]).
11. Opioid antagonists (methylnaltrexone, naloxone, naloxegol, alvimopan, axelopran, or naldemedine) are effective (more so than laxatives) and safe to treat opioid-induced constipation (**S**) (**Level I** [PRISMA]).
12. Alvimopan is an effective treatment for postoperative ileus (**U**) (**Level I** [QUOROM]).
13. Haloperidol, perphenazine and transdermal scopolamine are effective in the prevention of postoperative nausea and vomiting (**U**) (**Level I**).
14. The incidence of clinically meaningful adverse effects (nausea, vomiting) of opioids is dose-related (**U**) (**Level I**).

15. Paired combinations of $5HT_3$ antagonists, droperidol or dexamethasone provide superior prophylaxis of postoperative nausea and vomiting than either compound alone (**U**) (**Level I**).
16. Naloxone, naltrexone, droperidol (**U**), nalbuphine (**S**) (**Level I**) and ondansetron (**N**) (**Level I** [PRISMA]) are effective treatments for opioid-induced pruritus.
17. Opioids administered by PCA, in particular morphine, show higher analgesic efficacy in females than in males (**U**) (**Level I**).
18. Tapentadol has similar efficacy to conventional opioids with a reduced rate of gastrointestinal adverse effects (nausea, vomiting, constipation) (**S**) (**Level I**).
19. Tramadol has a lower risk of respiratory depression and impairs gastrointestinal motor function less than other opioids at equianalgesic doses (**U**) (**Level II**).
20. Pethidine is not superior to morphine or hydromorphone in treatment of pain of renal colic (**U**) (**Level II**).
21. Morphine-6-glucuronide is an effective analgesic (**U**) (**Level II**).
22. In the management of acute pain, one opioid is not superior to others but some opioids are better in some patients (**U**) (**Level II**).
23. High doses of methadone can lead to prolonged QT interval (**U**) (**Level II**).
24. Opioid antagonists are effective treatments for opioid-induced urinary retention (**U**) (**Level III-1**).
25. Pethidine use is associated with an increased risk of delirium in the postoperative period compared to other opioids (**S**) (**Level III-2 SR**).
26. In clinically relevant doses, there is a ceiling effect for respiratory depression with buprenorphine but not for analgesia (**U**) (**Level III-2**).
27. Tapentadol has lower rates of abuse and doctor shopping than oxycodone (**S**) (**Level III-2**).
28. Opioid-related adverse effects in the postoperative period are associated with increased inpatient mortality, length of hospital stay, costs and rates of readmission (**S**) (**Level III-2**).
29. Assessment of sedation is a more reliable way of detecting early opioid-induced ventilatory impairment than a decreased respiratory rate (**S**) (**Level III-3**).
30. The evidence for significant QT prolongation and risk of cardiac arrhythmias following low-dose droperidol, haloperidol and dolasetron is weak (**U**) (**Level III-3**).
31. Opioid-induced ventilatory impairment occurs in particular in the first 24 h after surgery and important risk factors are cardiac and pulmonary disease, obstructive sleep apnoea and use of higher opioid doses (**N**) (**Level IV SR** [PRISMA]).
32. Continuous pulse oximetry in patients receiving opioids postoperatively increases detection rate of desaturation, but continuous capnography is superior in identifying episodes of opioid-induced ventilatory impairment (**N**) (**Level IV SR** [PRISMA]).
33. In adults, patient age rather than weight is a better predictor of opioid requirements, although there is a large interpatient variation (**U**) (**Level IV**).

34. Impaired renal function and the oral route of administration result in higher levels of the morphine metabolite morphine-6-glucuronide with increased risk of sedation and respiratory depression (**U**) (**Level IV**).

34. CYP2D6 ultrarapid metabolisers are at increased risk of codeine toxicity (**N**) (**Level IV**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Opioid-induced ventilatory impairment is a more appropriate term to describe the effects of opioids on ventilation as it encompasses the central respiratory depression caused by opioids and also the depressed consciousness and the subsequent upper airway obstruction resulting from excessive opioid use (**U**).

☑ The use of pethidine and dextropropoxyphene should be discouraged in favour of other opioids (**S**).

☑ Drug interactions relevant for opioids include pharmacodynamic considerations (eg coadministration of sedative agents) and pharmacokinetic effects (eg CYP 450 enzyme inducers or inhibitors [antidepressants for CYP2D6 and antifungals, antibiotics for CYP3A4 and complementary medicines for both]) (**N**).

4.3.2 | Neuraxial opioids

Opioid receptors were described in the spinal cord of the rat in 1976 (Pert 1976 **BS**) and the same year a potent analgesic effect of directly applied IT morphine was reported in these animals (Kontinen 2019 **NR**; Yaksh 1976 **BS**). Opioid analgesia is spinally mediated via presynaptic and postsynaptic receptors in the substantia gelatinosa in the dorsal horn (Yaksh 1981 **BS**). Spinal opioid receptors are 70% mu, 24% delta and 6% kappa (Treman 2001 **NR**); with 70% of all mu and delta receptors being presynaptic (predominantly small primary afferents) and commonly co-located, with kappa being more commonly postsynaptic. Opioid-mediated antinociception may be further augmented by descending inhibition from mu-opioid-receptor activation in the periaqueductal area of the brain, which may be potentiated by neuraxial opioids. In addition to this, a local anaesthetic action has been described for pethidine (meperidine) that may contribute to the clinical effect when administered IT (Jaffe 1996 **BS**). The first clinical use of IT morphine was for analgesia in cancer patients (Wang 1979 **Level IV**).

The use of neuraxial opioids has been reviewed in paediatric patients (Berger 2019 **NR**) (see sections 10.6.4 for use in paediatric cardiac and general surgery and section 10.6.6 for use in paediatric scoliosis surgery) and obstetric populations (Armstrong 2016 **NR**). Its use is widespread in the obstetric and gynaecological setting for provision of analgesia in labour, Caesarean section and hysterectomy (Hein 2017 **Level IV**, n=32 [obstetric units in Sweden]). See also Section 9.1.3.3.

Although dose-response analyses are not always clear, it is suggested that neuraxial opioids have a ceiling effect for analgesia, with optimal single-injection morphine doses (balancing risk-benefit) of 50 to 150 mcg IT and 2.5 to 3.75 mg via epidural route (Saltan 2011 **NR**).

4.3.2.1 | Efficacy of intrathecal opioids

IT opioids have been used for surgical procedures ranging from lower limb orthopaedic surgery to CABG surgery because of their ability to provide prolonged postoperative analgesia following a single dose vs systemic administration. IT opioids may be given alone or in conjunction with a local anaesthetic. In acute pain, the use of continuous subarachnoid infusions of opioids for postoperative analgesia is uncommon.

The lipid solubility of opioids largely determines the speed of onset and duration of IT analgesia; hydrophilic opioids (eg oxycodone, morphine, hydromorphone) have a slower onset of action and longer half-lives in CSF with greater dorsal horn bioavailability and greater cephalad migration vs lipophilic opioids (eg fentanyl) (Bujedo 2014 **NR**; Bernards 2003 **NR**).

Single injection IT opioids

Early clinical studies used very high IT morphine doses (ie ≥500 mcg). However adequate postoperative analgesia with fewer adverse effects may be obtained with significantly less morphine; although at lower doses there is not a clear dose-response relationship for pain relief or some adverse effects (see below) (Meylan 2009 **Level I**, 27 RCTs, n=1,205).

Low doses of IT morphine are effective in prolonging local anaesthetic block or reducing the dose of local anaesthetic required for spinal anaesthesia with reduced adverse effects and improved recovery (Popping 2013 **Level I** [PRISMA], 28 RCTs; n=1,393; Popping 2012 **Level I** [PRISMA], 55 RCTs; n=3,338).

When combined with low-dose bupivacaine for Caesarean section, 100 mcg IT morphine produced analgesia comparable with doses as high as 400 mcg, with significantly less pruritus (Girgin 2008 **Level II**, n=100, JS 4). A single dose of IT morphine (100 mcg) added to a spinal anaesthetic for Caesarean section prolongs the time to first postoperative analgesic administration by 16 to 20 h (Dahl 1999 **Level I**, 15 RCTs, n=535). Sufentanil (2 RCTs) and fentanyl (8 RCTs) showed little or no analgesic benefit in doses of 25 mcg or less. No differences in pain reported or analgesia use was detected when comparing 100 mcg to 50 mcg IT morphine for Caesarean section, although pruritus was more common in the higher-dose group (Carvalho 2013 **Level II**, n=130, JS 4).

IT morphine 100, 200 and 300 mcg added to bupivacaine for postoperative analgesia following abdominal hysterectomy reduced IV PCA morphine consumption vs placebo, with no additional benefit of 300 mcg vs 200 mcg (Hein 2012 **Level II**, n=144, JS 5).

The addition of IT fentanyl 25 mcg to low-dose spinal bupivacaine for anorectal surgery resulted in more pruritus but lower mean recovery and discharge times, with fewer analgesic requests in the fentanyl group (Gurbet 2008 **Level II**, n=40, JS 3). Tramadol 10 and 25 mg administered IT with bupivacaine produces extension of spinal analgesia and prolonged postoperative analgesia similar to comparative doses of fentanyl 10 and 25 mcg for Caesarean section (Subedi 2013 **Level II**, n=80, JS 5) and appendectomy (Afolayan 2014 **Level III-1**, n=186).

Added to hyperbaric bupivacaine 10 mg (2 mL 0.5%), IT sufentanil 5 mcg provided shorter postoperative analgesia (mean 6.3 h) than IT morphine 200 mcg (mean 19.5 h) with no difference in adverse effects (Karaman 2006 **Level II**, n=54, JS4).

In a non-blinded comparison, following Caesarean section IT morphine 100 mcg recipients had longer analgesia and fewer intraoperative adverse effects vs IT pethidine 10 mg recipients but experienced more pruritus (Kumar 2007 **Level II**, n=60, JS 2). IT pethidine 25 mg added to lidocaine with adrenaline for spinal anaesthesia had quicker onset with higher sensory block and more prolonged time to significant pain (≥4/10) (9.6 h) vs IT fentanyl 25 mcg (6.3 h) or placebo (2.1 h) (Farzi 2014 **Level II**, n=195, JS 5).

Combination IT opioids

The addition of 10 mcg sufentanil to 400 mcg IT morphine did not potentiate postoperative analgesia or reduce intraoperative opioid requirements in patients undergoing major colorectal surgery (Culebras 2007 **Level II**, n=80, JS 5).

IT opioid infusions

In the ICU, IT infusion of morphine has been reported as a method to control burns pain and thereby avoiding the adverse effects of systemic opioids (Zuehl 2018 **CR**). IT morphine has also been administered in bolus doses via a 22-g IT catheter placed at L 3/4 to provide analgesia after thoracotomy (mean dose over 48 h 2.56 mg ± SD 0.88) with no serious complications or sequelae at 6 mth follow-up (Ward 2014 **Level IV**, n=84).

For further details on effectiveness and adverse effects related to the use of IT opioids see Section 4.3.2.3 below and 5.7.1.2.

4.3.2.2 | Efficacy of epidural opioids

The behaviour of epidural opioids is governed largely by their lipid solubility. The greater sequestration of lipid soluble opioids into epidural fat and slow rerelease back into the epidural space means that elimination from the epidural space is prolonged, resulting in relatively smaller fractions of medication reaching the CSF (Bernards 2003 **NR**). Lipophilic opioids (eg fentanyl) have a faster onset but shorter duration of action vs hydrophilic opioids (eg morphine) (Bujedo 2014 **NR**; Bernards 2004 **NR**; de Leon-Casasola 1996 **NR**).

A meta-analysis of randomised studies involving epidural opioids, mostly in combination with local anaesthetics, found no differences in VAS pain scores at any time after surgery between opioids, although there was a higher rate of nausea and vomiting (OR 1.95; 95%CI 1.14 to 3.18) with morphine vs fentanyl (Youssef 2014 **Level I** [PRISMA], 24 RCTs, n=1,513). No studies directly compare epidural morphine and fentanyl alone for postoperative analgesia.

Epidural diamorphine

Diamorphine (diacetylmorphine, heroin) is rapidly hydrolysed to 6-mono-acetylmorphine (6-MAM) and morphine. Diamorphine and 6-MAM are more lipid soluble than morphine and penetrate the CNS more rapidly, although it is 6-MAM and morphine that are thought to be responsible for the analgesic effects of diamorphine (Miyoshi 2001 **NR**). Epidural administration of diamorphine is common in the UK and is effective whether administered by intermittent bolus dose or infusion (McLeod 2005 **Level II**, n=62, JS 5).

Epidural fentanyl

The evidence that epidural fentanyl acts via a spinal rather than systemic effect is conflicting and it has been suggested that any benefit when comparing epidural with systemic fentanyl alone is marginal (Bernards 2004 **NR**; Wheatley 2001 **NR**). However, the conflicting results may be due to differing techniques of administration. A lumbar epidural infusion of fentanyl appears to produce analgesia by uptake into the systemic circulation, whereas a bolus dose of fentanyl produces analgesia by a selective spinal mechanism (Ginosar 2003 **Level IV EH**, n=10). Thoracic epidural administration does appear to produce greater spinal analgesia, an effect more pronounced with coadministration with adrenaline, which provides a supra-additive effect possibly via both pharmacokinetic (via vasoconstriction, increasing the amount of epidural fentanyl available to spinal cord site of action) and pharmacodynamic (via alpha-2 adrenoceptor antinociceptive) mechanisms (Niemi 2013 **NR**). Less intraoperative fentanyl is required when administered via a thoracic epidural catheter vs IV administration for colon surgery, with longer time to first

postoperative analgesia request (Sadurni 2013 **Level II**, n=30, JS 4). There is no evidence of benefit of epidural vs systemic administration of alfentanil or sufentanil (Bernards 2004 **NR**).

Epidural hydromorphone

The quality of epidural analgesia with hydromorphone is similar to morphine (Chaplan 1992 **Level II**, n=55, JS 5). In a comparison of epidural and IV hydromorphone, patients required twice as much IV hydromorphone to obtain the same degree of analgesia (Liu 1995 **Level II**, n=16, JS 3).

Epidural morphine

Morphine is the least lipid soluble of the opioids administered epidurally; it has the slowest onset and offset of action (Cousins 1984 **NR**) and the highest bioavailability in the spinal cord after epidural administration (Bernards 2004 **NR**). As morphine has a prolonged analgesic effect, it can be given by intermittent bolus dose or infusion; the risk of respiratory depression may be higher and analgesia less effective with bolus dose regimens (de Leon-Casasola 1996 **NR**). The low lipid solubility makes level of administration of epidural morphine less relevant after blunt chest wall trauma with no difference in any outcome between thoracic and lumbar epidural morphine administration (Hakim 2012 **Level II**, n=55, JS 3).

Extended-release epidural morphine

An extended-release (ER) suspension of morphine has been developed for epidural use (Depodur™) consisting of morphine molecules suspended in liposome complexes (lipofoam). ER epidural morphine (EREM) was effective vs placebo after THA (Martin 2006 **Level II**, n=126, JS 5; Viscusi 2005 **Level II**, n=200, JS 5) and, using doses of ≥10 mg, to lead to better pain relief vs standard epidural morphine (4 or 5 mg) and reduced need for supplemental analgesics up to 48 h after THA (Viscusi 2006 **Level III-1**, n=39), lower abdominal surgery (Gambling 2005 **Level II**, n=541, JS 4) and Caesarean section (Carvalho 2007 **Level II**, n=70, JS 5; Carvalho 2005 **Level II**, n=79, JS 3). A pooled analysis of six clinical studies described consistent prolonged pharmacokinetics vs standard epidural morphine, with 25% higher peak plasma concentrations in women, mainly explained by differences in body weight (Viscusi 2009 **PK**).

EREM has provided superior analgesia vs continuous femoral nerve block (FNB) after TKA; however, only at rest at 24 h (Johnson 2011 **Level II**, n=65, JS 3). There were no differences in functional outcomes and adverse effects except for more pruritus with EREM but patients reported greater satisfaction with EREM. In two patients, EREM was used successfully after multiple rib fractures (Ford 2012 **Level IV**). After lumbar spinal surgery, EREM provided similar analgesia with fewer adverse effects than epidural morphine (Vineyard 2014 **Level II**, n=60, JS 3). IT morphine 7.5 mcg/kg vs EREM 150 mcg/kg had similar time to first PCA use and similar postoperative morphine IV use over 0 to 48 h in children (8 to 17 y) undergoing posterior spinal fusion for scoliosis repair (Cohen 2017 **Level II**, n=71, JS 4). Pain scores differed relating to the kinetics of the epidural preparation and were lower with IT morphine from 0 to 4 h, similar from 8 to 24 h, and lower with extended release epidural morphine from 28 to 36 h.

OIVI is more likely with EREM than IV PCA opioids (OR 5.74; 95%CI 1.08 to 30.5) (Sumida 2009 **Level I**, 3 RCTs, n=464). It has been recommended that the liposome preparation of EREM not be administered while local anaesthetics are present in the epidural space as this may cause early release of the morphine (Viscusi 2009 **PK**). When EREM was administered within 3 to 15 min of a 3 mL test dose of 1.5% lidocaine with adrenaline, higher serum morphine maximum concentration (C_{max}) values were reported vs C_{max} values when no lidocaine was administered; there was no difference in morphine C_{max} if the interval was >30 min. The C_{max} of morphine was unchanged when EREM doses were given 15, 30 and 60 min after an anaesthetic dose of epidural bupivacaine 0.25% 20 mL (Gambling 2009 **PK**) although, in a later study, peak plasma morphine concentrations were increased when administered 1 h post a high volume anaesthetic dose (2%

lidocaine with adrenaline, 20 to 35 mL) after Caesarean section, with associated increased morphine-related adverse effects (Atkinson Rallis 2011 **Level II**, n=30, JS 3).

Epidural oxycodone

There is limited safety data for neuraxial oxycodone (Lamminsalo 2019 **Level III-1 PK**, n=30; Olczak 2017 **Level IV**, n=11; Kokki 2016 **BS).** After Caesarean section, patients given epidural oxycodone 3 mg vs epidural morphine 3 mg had higher pain scores up to 24 h with slightly less pruritus (Sng 2016 **Level II**, n=100, JS 4). Epidural oxycodone was superior to IV oxycodone in gynaecological laparotomy, resulting in less rescue analgesia up to 4 h (Piirainen 2018 **Level II**, n=30, JS 5). The addition of epidural oxycodone to ropivacaine in labour analgesia was superior to ropivacaine alone, with lower pain scores for 4 h and longer duration of analgesia (Zhong 2020 **Level II**, n=80, JS 5).

Epidural pethidine

Pethidine is effective when administered epidurally by bolus dose, continuous infusion and by patient-controlled epidural analgesia (PCEA). It is more lipid soluble than morphine (but less than fentanyl and its analogues); thus its onset and offset of epidural analgesic action is more rapid than morphine (Ngan Kee 1998 **NR**). The analgesic effect of smaller doses appears to be spinally mediated but systemic effects are likely after larger doses; in the smaller doses it is not known whether the local anaesthetic properties of pethidine contribute significantly to pain relief (Ngan Kee 1998 **NR**). Epidural pethidine has been used predominantly in the obstetric setting. After Caesarean section epidural pethidine resulted in better pain relief and less sedation than IV pethidine (Paech 1994 **Level II**, n=45, JS 5) but inferior analgesia vs IT morphine, albeit with less pruritus, nausea and drowsiness (Paech 2000 **Level II**, n=144, JS 5).

Epidural sufentanil

Epidural sufentanil has been mainly used in labour analgesia; for details see Section 9.1.3.3.

Epidural buprenorphine

Epidural buprenorphine has been used in a limited number of studies in the past with no recent publications; a detailed review of the neuraxial use of buprenorphine has been published (Kosel 2016 **NR**).

Epidural tramadol

For lumbar epidural analgesia after thoracotomy, tramadol 100 mg vs morphine 4 mg resulted in comparable analgesia quality of shorter duration with less sedation and less decrease in arterial oxygenation (Turker 2005 **Level II**, n=40, JS 4). For epidural analgesia in labour, tramadol 5 mg/mL vs fentanyl 3 mcg/mL added to ropivacaine 0.125% had similar efficacy and adverse effects (Fan 2011 **Level II**, n=61, JS 5).

For paediatric use see Section 10.4.4.12.

4.3.2.3 | Adverse effects of neuraxial opioids in general

Opioid-induced ventilatory impairment

The prevalence of OIVI (author-reported) with use of neuraxial diamorphine and morphine after Caesarean section is 61/10,000 (95%CI 51 to 74) (Sharawi 2018 **Level IV SR**, 78 studies [54 RCTs, 21 studies & 3 case reports], n=18,455). However, when classified as clinically significant OIVI, highest prevalence with all doses of neuraxial opioids was 8.67/10,000 (95%CI 4.20 to 15.16) and lowest was 5.96/10,000 (95%CI 2.23 to 11.28). These rates dropped even further with the use of lower but clinically relevant doses of neuraxial morphine: IT dose ≤150 mcg 1.63/10,000 (95%CI 0.62 to 8.77) (31 RCTs [IT]) or epidural dose ≤3 mg 1.08/10,000 (95%CI 0.24 to 7.22) (32 RCTs

[epidural]). No cases were reported for IT diamorphine ≤400 mcg or epidural diamorphine ≤5 mg.

Practice guidelines for the prevention, detection and management of respiratory depression caused by neuraxial opioids have been published (ASA 2016 **GL**).

Nausea and vomiting

IV dexamethasone reduces the need for rescue antiemetics for PONV caused by long-acting neuraxial opioids (RR 0.44; 95%CI 0.35 to 0.56) (Grape 2018 **Level I** [PRISMA], 13 RCTs, n=1,111).

4.3.2.4 | Adverse effects of intrathecal opioids

Depending on type and dose of the opioid, a combination of spinal and systemic (supraspinal) mechanisms may be responsible for adverse effects associated with intrathecal opioids. Many of these effects are more frequent with morphine and are to some extent dose-related (Dahl 1999 **Level I**, 15 RCTs, n=535; Cole 2000 **Level II**, n=38, JS 4).

Opioid-induced ventilatory impairment

Late onset respiratory depression (>2 h after administration), which is believed to be a result of the cephalad spread of opioids to the medulla within the cerebrospinal fluid (CSF), is also seen more commonly with hydrophilic opioids such as morphine and hydromorphone and appears to match the time taken for trigeminal analgesia, which is approximately 6 to 12 h after administration (Bujedo 2014 **NR**; Saltan 2011 **NR**; Cousins 1984 **NR**).

A single dose of IT morphine 100 mcg added to a spinal anaesthetic for Caesarean section was associated with low rate of respiratory depression (Dahl 1999 **Level I**, 15 RCTs [12 respiratory depression], n=535). A meta-analysis comparing IT morphine doses <300 mcg, ≥300 mcg and placebo reported a greater risk of respiratory depression with the higher vs the lower doses of morphine (Gehling 2009 **Level I,** 28 RCTs, n=1,314). In combination with bupivacaine, IT morphine 50 to 2,000 mcg was associated with more respiratory depression than IT fentanyl 10 to 50 mcg (3.4% vs 0.4%) (Popping 2013 **Level I** [PRISMA], 28 RCTs; n=1,393; Popping 2012 **Level I** [PRISMA], 55 RCTs; n=3,338).

The incidence of respiratory depression with the lipophilic opioid fentanyl given via the epidural route has been reported to be 1.4% (with 0.4% requiring naloxone) (Scott 1995a **Level IV**, n=1,297) but, when given IT, fentanyl or sufentanil are likely to be lower risk than the hydrophilic opioids morphine and hydromorphone (Horlocker 2009 **GL**).

Risk factors for respiratory depression include higher doses (>300 mcg morphine), increasing age, obesity and coadministration of systemic opioids or sedatives (Saltan 2011 **NR**). A detailed analysis of sustained hypercapnia events (transdermal CO_2 >50 mm Hg for ≥2 min) after IT administration of hyperbaric bupivacaine 12 mg , fentanyl 15 mcg and morphine 150 mcg for Caesarean section revealed an incidence of 32% (Bauchat 2017 **Level IV**, n=120). Events occurred at a median of 300 min after IT administration with a median number of 3 events and longest duration of 26 min.

Nausea and vomiting

A meta-analysis comparing IT morphine doses <300 mcg vs ≥300 mcg and placebo reports increased nausea (RR 1.4; 95%CI 1.1 to 1.7) and vomiting (RR 3.1; 95%CI 1.5 to 6.4) in the higher dose group (Gehling 2009 **Level I,** 28 RCTs, n=1,314). A single dose of morphine 100 mcg added to a spinal anaesthetic for Caesarean section was associated with nausea (10%) and vomiting (12%) (Dahl 1999 **Level I**, 15 RCTs [11 nausea & 8 vomiting], n=535).

Pruritus

A meta-analysis comparing IT morphine doses <300 mcg vs ≥300 mcg and placebo reports increased pruritus (RR 1.8; 95%CI 1.4 to 2.2) in the higher dose group (Gehling 2009 **Level I,** 28 RCTs,

n=1,314). A single dose of morphine 100 mcg added to a spinal anaesthetic for Caesarean section was associated with pruritus (43%) (Dahl 1999 **Level I**, 15 RCTs [11 pruritus], n=535). For Caesarean section, IT morphine 50 mcg vs IT morphine 100 mcg resulted in a lower rate of pruritus (70% vs 87%) (Carvalho 2013 **Level II**, n=130, JS 4).

Neurotoxicity

Clinical experience with morphine, fentanyl and sufentanil has shown no neurotoxicity or behavioural changes at clinically used IT doses (Hodgson 1999 **Level IV**). Other opioid agonists or partial agonists do not have animal or human safety data.

Tolerance

Tolerance to spinal opioid analgesia can develop rapidly. Low-dose mu and delta opioid antagonists can prevent tolerance development and restore morphine IT analgesia in animals (Abul-Husn 2007 **BS**). In an animal model, bolus doses increased nociceptive thresholds for 3 to 5 h followed by delayed hyperalgesia with a lower threshold lasting 1 to 2 d, an effect prevented by coadministration of ketamine (Van Elstraete 2005 **BS**). The clinical implications of single-dose neuraxial opioid administration in regard to the potential development of OIH or tolerance is uncertain. IT fentanyl added to bupivacaine and morphine for Caesarean section was associated with higher pain scores (the authors suggesting acute tolerance) but no difference in 24 h morphine consumption (Carvalho 2012 **Level II**, n=40, JS 5). Adding fentanyl to IT local anaesthesia for Caesarean section improved anaesthesia conditions but was associated with a 60% increase in morphine consumption between 6 and 24 h (Cooper 1997 **Level II**, n=60, JS 2). IT sufentanil was associated with wound hyperalgesia (at 48 h), with a preventive effect demonstrated by addition of 150 mcg IT clonidine (Lavand'homme 2008 **Level II**, n=96, JS 5). Ondansetron is assumed to ameliorate opioid-induced hyperalgesia and tolerance in animal studies; however, IV ondansetron 8 mg vs placebo administered before spinal anaesthesia for Caesarean section (IT bupivacaine 15 mg, IT fentanyl 20 mcg and IT morphine 100 mcg) had no effect on postoperative pain scores or opioid consumption (Greer 2017 **Level II**, n=86, JS 5).

For more details on epidural opioid use see Section 5.6. and in particular 5.6.2.2 and 5.6.2.3.

KEY MESSAGES

Intrathecal opioids

1. Intrathecal morphine and intrathecal fentanyl prolong spinal local anaesthetic block, with fentanyl being associated with fewer adverse effects (**U**) (**Level I** [PRISMA]).
2. Intrathecal morphine produces better postoperative analgesia than intrathecal fentanyl or sufentanil after Caesarean section (**U**) (**Level I**).
3. Intrathecal morphine doses of 300 mcg or more increase the risk of respiratory depression (**U**) (**Level I**).

Epidural opioids

4. Epidural morphine provides similar analgesia to epidural fentanyl when combined with local anaesthetic, although the incidence of nausea is greater with morphine (**U**) (**Level I** [PRISMA]).
5. Extended-release epidural morphine provides analgesia for up to 48 hours (**U**) (**Level II**), however it is associated with more respiratory depression than intravenous PCA following abdominal surgery (**U**) (**Level I**).

6. Epidural pethidine produces better pain relief and less sedation than intravenous pethidine after Caesarean section (**U**) (**Level II**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ No neurotoxicity has been shown at normal clinical intrathecal doses of morphine, fentanyl and sufentanil (**U**).

☑ Neuraxial administration of bolus doses of hydrophilic opioids carries an increased risk of delayed sedation and respiratory depression compared with lipophilic opioids (**U**).

4.3.3 | Peripheral opioids

Opioid receptors are expressed in peripheral sensory neurons in both animals and humans (Stein 2013 **NR**; Stein 2011 **NR**). Multiple mechanisms have been proposed to explain the clinical observation that peripheral opioids are more effective in the presence of tissue injury or inflammation. Further research into the role of peripheral opioids in clinical models of inflammatory pain is recommended; the acute postoperative period may not allow sufficient time for the upregulation of peripheral opioid receptors.

Peripherally applied opioids (excluding IA, perineural and mucosal administration) for post-operative pain relief vs placebo or systemic administration do not have any clinically relevant effects (Nielsen 2015a **Level I** [PRISMA], 26 RCTs, n=1,531).

However, peripherally applied opioids had an analgesic effect, when injected into areas with preoperative inflammation (Stein 2013 **NR**; Stein 2011 **NR**). Consequently, submucosal injection of morphine 2 mg into inflamed tissue after tooth extraction (under a standard local anaesthesia) resulted in lower pain on swallowing and prolonged post-operative analgesia vs IM injection and vs injection into non-inflamed tissue of the same dose of morphine (Akural 2016 **Level II**, n=81, JS 5).

4.3.3.1 | Intra-articular

Morphine

IA administration is the most extensively examined clinical application of peripheral opioid therapy (Stein 2013 **NR**). In experimentally induced synovitis in horses, IA morphine reduced clinical and biological signs of inflammation vs IV administration (Lindegaard 2010 **BS**).

IA bupivacaine was less effective than morphine in providing analgesia in patients having "high inflammatory arthroscopic knee surgery", whereas bupivacaine was more effective than morphine in those having "low inflammatory surgery" (Marchal 2003 **Level II**, n=53, JS 5).

IA morphine in a dose of 1 mg is not better than placebo at reducing pain at early, medium or late stages post arthroscopy (7 RCTs, n=297) (Zou 2016 **Level I** [Cochrane], 28 RCTs, n=2,564). IA morphine 1 mg was not more effective than IA bupivacaine, NSAIDs, sufentanil, fentanyl and pethidine. There was no difference in pain relief between IM morphine vs IA morphine at any time point (2 RCTs, n=73); the latter results are in line with another RCT not included in the meta-analysis (Cepeda 1997 **Level II**, n=112, JS 5).

Morphine/bupivacaine vs bupivacaine alone leads to reduced pain scores (WMD −1.15/10; 95% CI −1.67 to −0.63) without an effect on time to first analgesic request and requirements for supplementary analgesia and with no increase in side effects (Yang 2017b **Level I** [PRISMA], 29 RCTs,

n=1,116). However following arthroscopy, morphine/bupivacaine increased postoperative analgesia requirements and side effects vs tenoxicam/bupivacaine (Sanel 2016, **Level II**, n=240, JS 5).

Other opioids

IA tramadol 50-100 mg administered as an adjunct to bupivacaine reduces postoperative pain and increases time to breakthrough analgesia requirements without increasing side effects after arthroscopy (Ryan 2019 **Level I**, 6 RCTs, n=334). The combination of IA pethidine (meperidine)/bupivacaine had synergistic analgesic effect vs either medication alone (Imani 2015 **Level II**, n=60, JS 5). IA fentanyl/bupivacaine did not reduce reported pain scores and postoperative analgesia requirement vs bupivacaine alone or midazolam/bupivacaine in an underpowered RCT (Nahravani 2017, **Level II**, n=45, JS 5). IA administration of morphine/levobupivacaine/tenoxicam provided superior analgesia to a combination of tramadol/levobupivacaine/tenoxicam or saline placebo (Oral 2015 **Level II**, n=90, JS 5). Levobupivacaine 0.25% for arthroscopic knee surgery combined with either fentanyl or tramadol provided superior analgesia vs levobupivacaine alone for day case arthroscopic knee surgery (Sayin 2015 **Level II**, n=80, JS 4). The addition of IA sufentanil to a mixture of ropivacaine and clonidine following anterior cruciate ligament repair provided no additional analgesic benefits (Armellin 2008 **Level II**, n=120, JS 5).

The evidence for IA morphine, tramadol, buprenorphine, fentanyl and NSAIDs was inconclusive due to a small number of low-quality studies for temporomandibular joint arthrocentesis (Gopalakrishnan 2018 **Level IV SR** [PRISMA], 6 studies, n=433 [3 RCTs, n=91]).

There are no comparisons between IA and systemic administration of these opioids alone.

4.3.3.2 | Perineural

An initial meta-analysis found no evidence for analgesic efficacy of peripheral opioids with perineural block by local anaesthetics (Picard 1997 **Level I**, 26 RCTs, n=952). Since this publication, more research has been conducted.

Buprenorphine

The addition of perineural buprenorphine 0.1 to 0.3 mg to local anaesthetics prolongs the duration of analgesia provided by nerve blocks vs placebo (MD 8.64 h; 95%CI 6.44 to 10.85) (9 RCTs, n= 510), but is associated with significant increases in PONV (RR 5.0; 95%CI 1.12 to 22.27) (3 RCTs, n=210) (Schnabel 2017 **Level I** [PRISMA], 13 RCTS, n=685). In comparison to systemic (IM) administration of buprenorphine, perineural administration prolongs duration of analgesia (MD 6.87 h, 95%CI 4.02 to 9.71) (5 RCTs, n=294) without increasing PONV. The findings are qualified by the description of high risk of publication bias and heterogeneity in the results obtained. A subsequent RCT found no difference in time to first rescue analgesia comparing a femoral nerve block for TKA with either perineural or SC buprenorphine 0.3 mg (van Beek 2017 **Level II**, n=65, JS 5). Adjuvant buprenorphine 0.3 mg vs adjuvant dexamethasone 4 mg added to levobupivacaine 0.25% 20 mL transverse abdominis plane block (TAPB) for inguinal hernia repair demonstrated longer times to rescue analgesia and lower mean postoperative tramadol consumption in the first 24 h vs placebo (saline 1 mL) (Seervi 2019 **Level II**, n=93, JS 4). Perineural administration of buprenorphine 0.15 mg and dexamethasone 4 mg vs IV administration of the same doses in conjunction with sciatic and adductor canal blocks for foot and ankle surgery resulted in longer block duration, lower scores for 'worst pain' and less nausea, but no difference in pain scores at 24 h (YaDeau 2015 **Level II**, n=90, JS 5).

Sufentanil

The addition of sufentanil 10 mcg to bupivacaine for ultrasound guided brachial plexus block for upper limb procedures prolonged the duration of both sensory and motor block in chronic opioid users and non-users (Azimaraghi 2015 **Level II**, n=120, JS 5). No difference was found in postoperative pain scores or supplemental analgesic requirements when fentanyl 100 mcg was administered with ropivacaine 0.75% in a femoral nerve block and then per perineural catheter infusion (3 mcg/mL fentanyl/ropivacaine 0.75%: basal rate 10 mL/h) vs ropivacaine alone (Heo 2016 **Level II**, n=82, JS 5).

Tramadol

Tramadol 100 mg as an adjuvant to brachial plexus block vs placebo prolonged analgesia (MD 125.5 min; 95% CI 73.3 to 175.8), but also sensory and motor block (Shin 2017 **Level I** [PRISMA], 16 RCTS, n=751); there were no comparisons to systemic administration.

Preoperative femoral nerve block for TKA with ropivacaine 0.375% 20 mL and adjuvant tramadol 100 mg was superior with lower pain scores (from 8 to 72 h), longer sensory and motor blockade and reduced requirement for postoperative PCA vs no femoral nerve block, femoral nerve block with ropivacaine only or femoral nerve block with ropivacaine/ tramadol 50 mg (Tang 2016 **Level II**, n=60, JS 1).

4.3.3.3 | Topical

While opioid receptors have been identified in the cornea and skin, topically applied opioids have not consistently demonstrated efficacy in pain states such as corneal ulceration (fentanyl) (Zollner 2008 **Level II**, n=40, JS 4), partial thickness burns (morphine) (Welling 2007 **Level II**, n=49, JS 5) or chronic skin ulceration (morphine) (Vernassiere 2005 **Level II**, n=18, JS 4).

The clinical use of topical opioids in palliative care for pain control in cutaneous lesions is reported as beneficial in three of six RCTs (Graham 2013b **Level IV SR**, 26 studies, n unspecified). A greater benefit was reported with inflammatory lesions than with vascular ulcers, suggesting an anti-inflammatory role of topical opioids may be as important as a peripheral analgesic benefit. Topical morphine (0.2% gel) and ointment for mucosal and skin lesions in palliative cancer patients reduced base line pain after 7 d of treatment ($NNT_{50\%}$ 1.67) with minimal side effects (Cialkowska-Rysz 2019, **Level II**, n=35, JS 4).

In chemotherapy-induced mucositis an analgesic dose-dependent effect was seen in a small pilot study using 1 mg/mL and 2 mg/mL morphine mouthwash (Cerchietti 2003 **Level III-1**). Benefit was also evident for morphine mouthwash 30 mg every 3 h, with a local anaesthetic-based solution, in mucositis associated with chemoradiotherapy in head and neck cancer patients (Cerchietti 2002 **Level II**, n=26, JS 3). With oral morphine mouthwash 2% (30 mg in 15 mL) for the treatment of mucositis pain, the act of mouth washing was beneficial, with early termination due to recruitment difficulty and indaequate power to detect benefit with morphine vs quinine placebo solution (Vayne-Bossert 2010 **Level II**, n=11, JS 5). Topical morphine mouthwash 2% (10 mL) for patients with severe mucositis associated with head and neck cancer treatment was more effective than a combination mouthwash (containing viscous lidocaine, magnesium aluminium hydroxide and diphenhydramine) 10 mL 3 hly over 6 d (Sarvizadeh 2015 **Level II**, n=30, JS 5). WHO grading scores for mucositis decreased in both groups at 6 d, but were lower in and with increased satisfaction in morphine recipients. See also Section 8.6.7.7 and 8.9.8.2.

KEY MESSAGES

1. Intra-articular morphine (1 mg) following knee arthroscopy does not improve analgesia compared with placebo (**S**) (**Level I** [Cochrane Review]).
2. Intra-articular morphine/bupivacaine following knee arthroscopy compared to bupivacaine alone improves analgesia without increasing adverse effects (**N**) (**Level I** [PRISMA]).
3. Perineural buprenorphine/local anaesthetic for peripheral nerve blocks compared to local anaesthetic and to systemic buprenorphine/local anaesthetic prolongs duration of analgesia (**N**) (**Level I** [PRISMA]).
4. Perineural tramadol/local anaesthetic for brachial plexus block compared to local anaesthetic alone prolongs duration of analgesia (**N**) (**Level I** [PRISMA]).
5. Peripherally applied opioids (excluding intra-articular, perineural and mucosal administration) show no clinically relevant analgesic effect (**N**) (**Level I** [PRISMA]).
6. Intra-articular tramadol/bupivacaine following knee arthroscopy compared to bupivacaine alone improves analgesia without increasing adverse effects (**N**) (**Level I**).
7. Morphine mouthwash may have analgesic effects in chemotherapy-induced mucositis (**N**) (**Level II**).
8. Evidence for intra-articular analgesic administration is inconclusive for temporomandibular joint arthrocentesis (**N**) (**Level IV SR** [PRISMA]).

4.4 | Local anaesthetics and other membrane stabilisers

Local anaesthetics (LA) act primarily by reversibly blocking neuronal voltage-gated sodium channels (VGSC) and thereby temporarily interrupting nerve impulse propagation. LA also have additional systemic effects which may be independent of action on the VGSC due to interaction with potassium channels, calcium channels, N-methyl-D-aspartate (NMDA) receptors, and G-protein coupled receptors (van der Wal 2016 **NR BS**; Lirk 2014 **BS**). The latter, via the $G_{q/11}$ subfamily, may contribute to the anti-inflammatory effects of LAs (Hollmann 2000 **NR**). Thus, the use of LAs beyond perineural applications is expanding.

Both amide and ester local anaesthetics have been found to have antimicrobial activity in concentrations used in clinical practice, with tetracaine, bupivacaine and lidocaine having the most marked activity (Razavi 2019 **NR BS**); these are not primary effects and are modified by a range of factors including the admixture of other drugs.

4.4.1 | Systemic local anaesthetics and other membrane stabilisers

IV lidocaine has analgesic, anti-inflammatory and antihyperalgesic properties and attenuates the neuroinflammatory response in perioperative pain and chronic neuropathic pain (van der Wal 2016 **Level IV SR**, 36 in vitro studies, 31 animal studies & 21 clinical studies [3 SRs & 7 RCTs in acute pain; 1 SR, 6 RCTs & 4 studies in chronic pain]). The safe dose and duration of perioperative IV lidocaine infusions has not been clearly established, with only limited total patient numbers and few adverse reactions having been reported in the literature to date (Bailey 2018 **Level I**, 6 RCTs, n=420; Masic 2018 **Level IV SR**, 13 studies, n= 512).

4.4.1.1 | Acute pain

A Cochrane review on IV lidocaine and analgesia (Kranke 2015 **Level I** [Cochrane], 45 RCTs, n=2,802) has been updated with a further 23 RCTs (Weibel 2018 **Level I** [Cochrane], 68 RCTs [66 vs placebo/no comparator; 2 vs epidural], n=4,525) finding small effects and uncertain outcomes. Lidocaine infusions at varying doses (1-5 mg/kg/h) for varying duration in various surgery types (open [22 RCTs] or laparoscopic [20 RCTs] abdominal and others [26 RCTs]) vs placebo or no treatment) reduces pain intensity to a limited extent 1 to 4 h postoperatively (SMD −0.50; 95%CI −0.72 to −0.28; 0.37/10 to 2.48/10) (29 RCTs, n=1,656), at 24 h (SMD −0.14; 95%CI −0.25 to −0.04) (33 RCTs, n=1,847) and at 48 h (SMD −0.11; 95%CI −0.25 to 0.04) (24 RCTs, n=1,404), noting that the results for these later time points represent less than a 1 point reduction in a 10 point pain scale. There is also a reduction of postoperative ileus (RR 0.37; 95%CI 0.15 to 0.87) (4 RCTs, n=273), time to first defaecation (MD −7.92 h; 95%CI −12.71 to −3.13) (12 RCTs, n=684), postoperative nausea 0 to 2 h (RR 0.78; 95%CI 0.67 to 0.91) (35 RCTs, n=1,903), opioid requirements (MD −4.52 MME; 95%CI −6.25 to −2.79) (40 RCTs, n=2,201) and LOS (MD −0.37 d; 95%CI −0.60 to −0.15) (32 RCTs, n=2,077). Vomiting overall was not impacted (OR 0.83; 95% CI 0.63 to 1.08) (19 RCTs, n=1026). IV lidocaine vs TEA has no effect on pain intensity and other outcomes (2 RCTS, n=102). The authors describe all these results as "*uncertain*" due to the quality of the evidence being limited by inconsistency, imprecision, and study quality.

In breast surgery, IV lidocaine administered intraoperatively and continued for up to 2 h is not associated with improved pain scores up to 72 h vs placebo controls, but opioid requirements were lower in the lidocaine group (Chang 2017 **Level I** [PRISMA], 3 RCTs, n=167); however, benefit was found in chronic postsurgical pain prevention. See Section 4.4.1.2 below.

After colonic surgery, IV lidocaine was associated with improved pain relief vs controls and also with decreases in proinflammatory cytokines, including interleukin-6 (IL-6), IL-8 and IL-1RA (a competitive inhibitor of IL-1β) (Kuo 2006 **Level II**, n=60, JS 5). For radical prostatectomy, a combination of intraoperative IV and postoperative SC lidocaine for up to 24 h vs saline reduced pain, morphine consumption and LOS (Weinberg 2016 **Level II**, n=76, JS 5). Following open nephrectomy, intraoperative IV lidocaine or IV ketamine continued for 24 h were both superior to placebo in reducing pain scores and 24 h opioid consumption (lidocaine 27.8 mg ± 5.5 and ketamine 32 mg ± 7.0 vs placebo 47.6 mg ± 5.0) (Jendoubi 2017 **Level II**, n=60, JS 4); IV lidocaine was associated with significantly lower pain scores at rest and with movement over 24 h vs IV ketamine. In radical cystectomy patients, the addition of perioperative IV lidocaine infusion for 6 h resulted in lower pain scores for up to 18 h (Moeen 2019 **Level II**, n=111, JS 5); recovery of bowel function was also improved.

Perioperative IV administration of lidocaine also has a preventive analgesic effect (extending beyond 5.5 half-lives of lidocaine, ie >8 h after cessation of administration) after a wide range of operations (Barreveld 2013a **Level I**, 16 RCTs, n=678) (15 RCTs overlap with Weibel 2018). See also Sections 1.4 and 1.5.

In the emergency department (ED), the efficacy of IV lidocaine in the treatment of nonsurgical acute pain has been reviewed, noting that dosing was not standardised and individual studies were small (Silva 2018 **Level IV SR**, 6 RCTs & 2 studies, n=536; Masic 2018 **Level IV SR** 4 RCTs & 9 studies, n= 512) (4 RCTs overlap); analgesic benefit is superior to placebo or comparable to active controls in renal colic (2 RCTs) and limb ischemia (1 RCT), but inconsistently in acute migraine (2 RCTs) and not in acute radicular low back pain (1 RCT). Although most non-randomised studies demonstrated improved analgesia with IV lidocaine, certainty with these findings is low. Safety data is limited with 20 adverse events (19 nonserious, 1 classified serious: overall rate 8.9%; 95%CI 5.5% to 13.4%) (6 studies, n=225) reported with IV lidocaine use in the ED (Silva 2018 **Level IV SR**, 6 RCTs and 2 studies, n=536).

IV lidocaine has a potentially analgesic effect in procedural pain in burns (Wasiak 2012 **Level I** [Cochrane], 1 RCT: Wasiak 2011 **Level II**, n=45, JS 5), however its role in this indication requires further investigation.

The use of IV lidocaine in an obese population undergoing laparoscopic gastric reduction surgery reduced pain scores, opioid consumption and improved quality of recovery (Sherif 2017 **Level II**, n=150, JS 5; De Oliveira 2014a **Level II**, n=50, JS 5).

Results for IN lidocaine are conflicting showing significant benefit (Maizels 1996 **Level II**, n=53, JS 2) and no effect (Blanda 2001 **Level II**, n=49, JS 4).

Mexiletine improved pain relief and reduced analgesic requirements after breast surgery (Fassoulaki 2002 **Level II**, n=75, JS 3).

4.4.1.2 | Chronic pain and transition to chronic pain

A meta-analysis found that IV lidocaine reduces chronic postsurgical pain at 3 mth vs placebo (OR 0.29; 95%CI 0.18 to 0.48) (Bailey 2018 **Level I** [PRISMA], 6 RCTs, n=420). In breast surgery patients, IV lidocaine administered intraoperatively and continued for up to 2 h has a lower risk for the development of chronic pain at 3 to 6 mth (RR 0.33; 95%CI 0.14 to 0.78) (Chang 2017 **Level I** [PRISMA], 2 RCTs, n=97) (2 RCTs overlap). See also Sections 1.4 and 1.5.

The membrane stabilisers IV lidocaine and mexiletine have a similar analgesic effect on neuropathic pain of various origins, which is superior to placebo (WMD 10.6; 95%CI -14.5 to -6.7) (Tremont-Lukats 2005 **Level I,** 19 RCTs, n=706) and similar to various comparators (Challapalli 2005 **Level I** [Cochrane], 30 RCTs, n=1,142). There was strong evidence of benefit for use of membrane stabilisers in pain due to peripheral nerve trauma (Kalso 1998 **Level I**, 17 RCTs, n=450). However, in

the guidelines for pharmacotherapy for neuropathic pain by the Special Interest Group on Neuropathic Pain (NeuPSIG) of the IASP, there is a strong recommendation against the use of mexiletine because of negative trials on efficacy and safety concerns (Finnerup 2015 **GL Level I** [PRISMA], 229 RCTs, n unspecified).

Currently, the use of membrane stabilisers for acute neuropathic pain can only be based on extrapolation of the above data.

KEY MESSAGES

1. Perioperative intravenous lidocaine reduces pain and opioid requirements to a limited extent following a range of surgery types, as well as nausea, but not vomiting, incidence and duration of ileus and length of hospital stay (**W**) (**Level I** [Cochrane Review]).
2. In breast surgery, perioperative lidocaine infusion does not improve pain scores for up to 72 hours, but is associated with lower acute opioid requirements and less chronic postsurgical pain at 3 to 6 months (**N**) (**Level I** [PRISMA])
3. Perioperative intravenous lidocaine has a preventive analgesic effect (extending beyond 5.5 half-lives of lidocaine, ie > 8 hrs after cessation of administration) after a wide range of operations (**U**) (**Level I**).

Chronic neuropathic pain and transition to chronic postsurgical pain

4. Both intravenous lidocaine and mexiletine are effective in the treatment of chronic neuropathic pain (**U**) (**Level I** [Cochrane Review]); however, guidelines advise against the use of mexiletine for this indication (**N**) (**GL Level I** [PRISMA]).
5. Perioperative IV lidocaine reduces chronic postsurgical pain at 3 months compared to placebo (**N**) (**Level I** [PRISMA]).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ The optimal and safe dose and duration of perioperative intravenous lidocaine infusions has yet to be clearly established (**N**).

☑ Based on the experience in chronic neuropathic pain states, it would seem reasonable to use membrane stabilisers including systemic lidocaine in the management of acute neuropathic pain (**U**).

☑ The role and safety of IV lidocaine for analgesia in the emergency department still requires clarification (N).

4.4.2 | Regional local anaesthetics

LAs exert their effect as analgesics by blocking sodium channels and hence impeding neuronal excitation and/or conduction. LAs differ predominantly by potency, duration of action and systemic toxicity.

4.4.2.1 | Short-duration local anaesthetics

Lidocaine is the most widely used short-duration LA in acute pain management. Although the plasma half-life is approximately 90 min, the duration of the LA effect depends very much on site of administration, dose administered and the presence or absence of vasoconstrictors. Although lidocaine is hydrophilic, it is delivered in high concentrations and therefore usually diffuses well into nerve bundles, resulting in little separation of sensory and motor blocking actions (Covino 1998 **NR**).

The use of lidocaine in ongoing acute pain management is usually restricted to the short-term re-establishment of a LA infusion block. It is generally considered unsuited to long-term (ie days) use because of the development of tachyphylaxis or acute tolerance, although the existing literature documenting the phenomenon of tachyphylaxis with neuraxial use of local anaesthetics is scarce and the mechanisms behind this phenomenon should it occur, is unclear (Kongsgaard 2016 **Level III-3** [PRISMA], 6 RCTs & 7 studies, n unspecified). Continuous perineural infusions of lidocaine for 24 h resulted in less effective analgesia and more motor block than infusions of the long-acting LA ropivacaine (Casati 2003c **Level II**, n=40, JS 4).

Mepivacaine is a short- to intermediate-duration LA agent, structurally related to bupivacaine and ropivacaine. Its use is largely restricted to intraoperative anaesthesia.

4.4.2.2 | Long-duration local anaesthetics

The three commonly used long-duration LAs, bupivacaine, levobupivacaine and ropivacaine, are structurally related (McLeod 2001 **NR**; Markham 1996 **NR**). Whereas bupivacaine is a racemic mixture of S- and R-enantiomers, levobupivacaine is the S(+)- (or levo-) enantiomer of bupivacaine; ropivacaine is likewise an S-enantiomer.

The issue with relative potency emerges with lower doses and concentrations of LAs. When doses are carefully titrated, a minimum local anaesthetic concentration (MLAC) can be found at which 50% of patients will achieve a satisfactory analgesic block. In obstetric epidural analgesia, two separate studies found the MLAC of bupivacaine was 0.6 times that of ropivacaine (Capogna 1999 **Level II**, n=87, JS 4; Polley 1999 **Level II**, n=83, JS 4). The motor-blocking potency showed a similar ratio of 0.66 (Lacassie 2003 **Level II**, n=60, JS 4).

When comparing bupivacaine with levobupivacaine, the “percentage” bupivacaine solution is by weight of bupivacaine hydrochloride, whereas the percentage levobupivacaine solution is for the active molecule alone. This means that the molar dose of equal “percentage concentration” is 13% higher for levobupivacaine (Schug 2001 **NR**). The sensory MLAC potency ratio of levobupivacaine to bupivacaine is 0.98, although if correction is made for molar concentrations this falls to 0.87 (neither value being significantly different from unity) (Lyons 1998 **Level II**, n=60, JS 3). Levobupivacaine has been shown to have slightly less motor-blocking capacity than bupivacaine with a levobupivacaine/bupivacaine potency ratio for epidural motor block of 0.87 (95%CI 0.77 to 0.98) (Lacassie 2003 **Level II**, n=60, JS 4). Another labour epidural analgesia study has found no difference in MLAC between levobupivacaine and ropivacaine with a ropivacaine/levobupivacaine potency ratio of 0.98 (95%CI 0.80 to 1.20) (Polley 2003 **Level II**, n=83, JS 4).

4.4.2.3 | Epidural local anaesthetics

For postoperative analgesia using epidural infusions, dose-ranging studies established that 0.2% ropivacaine was a suitable concentration (Schug 1996 **Level II**, n=36, JS 5; Scott 1995b **Level II**, n=30, JS 5). Therefore, most investigators compare infusions of bupivacaine or levobupivacaine at 0.1% or 0.125% with ropivacaine 0.2%, which removes any imbalance in comparative potency. In obstetric epidural analgesia, lower concentrations of epidural ropivacaine, typically 0.1%, are used in labour to avoid dense sensory and motor block (Zhang 2018 **SR Level IV**, 30 studies, n=2,851).

The majority of studies find similar analgesic outcomes with postoperative epidural infusions based on these strengths (Casati 2003b **Level II**, n=45, JS 5; Macias 2002 **Level II**, n=80, JS 5; Jorgensen 2000 **Level II**, n=60, JS 3). Motor block is of clinical relevance in low-thoracic or lumbar epidural infusions and has been reported to be less intense with epidural ropivacaine than with bupivacaine (Merson 2001 **Level II**, n=68, JS 4; Muldoon 1998 **Level II**, n=52, JS 4; Zaric 1996 **Level II**, n=37, JS 3). However, this finding has not been supported by another study (Casati 2003b **Level II**, n=45, JS 5).

The relevance of dose, not concentration or volume of LA infused, was confirmed in two trials. The same dose of a mixture of levobupivacaine in three different concentrations (0.5%, 0.25% and 0.15%) and sufentanil administered during continuous thoracic epidural infusion for thoracotomy resulted in similar efficacy and adverse effects (Mendola 2009 **Level II**, n=138, JS 3) as did two concentrations (0.15 and 0.5%) of levobupivacaine in another RCT (Dernedde 2006 **Level II**, n=82, JS 4). Neither infusions of bupivacaine 0.125% nor ropivacaine 0.2% interfered with neurophysiological assessments after scoliosis surgery (Pham Dang 2008 **Level II**, n=18, JS 4). At concentrations of ≥0.5%, there were no significant differences in onset time and intensity or duration of sensory block between bupivacaine, levobupivacaine or ropivacaine used for epidural analgesia (Casati 2003b **Level II**, n=45, JS 5; Cheng 2002 **Level II**, n=45, JS 3).

Local anaesthetic/opioid combinations

The quality of pain relief from low-dose epidural infusions of plain LA consistently benefits from the addition of opioids, most commonly fentanyl (Walker 2002 **Level I**, 4 RCTs [epidural local anaesthetic/opioid combinations], n=226; Curatolo 1998 **Level I**, 18 RCTs [fentanyl/local anaesthetic], n unspecified); this was confirmed by additional RCTs (Senard 2002 **Level II**, n=60, JS 3; Hubler 2001 **Level II**, n=109, JS 4; Crews 1999 **Level II**, n=64, JS 3; Scott 1999 **Level II**, n=182, JS 5;). For addition of other adjuvants see Sections 4.9, 4.12.2 and 4.13.

Potential dose-sparing benefits are more obvious for LA adverse effects (hypotension and motor block) than for opioid-related adverse effects (Walker 2002 **Level I**, 4 RCTs [epidural LA/opioid combinations], n=226).

Comparisons of PCEA using ropivacaine 0.2%, ropivacaine 0.125% and levobupivacaine 0.125%, all with sufentanil 1 mcg/mL (6 mL/h background plus 2 mL bolus), showed no differences in pain relief or motor block; patients given 0.2% ropivacaine used similar volumes, thus receiving more total dose of local anaesthetic and the same amount of sufentanil (Sitsen 2007 **Level II**, n=63, JS 4). Similarly, there was no difference in analgesia and no motor block reported in a PCEA comparison of ropivacaine 0.05%, 0.075% and 0.1%, with fentanyl 4 mcg/mL and droperidol 25 mcg/mL added to all solutions (Iijima 2007 **Level II**, n=272, JS 4). In another comparison of PCEA bupivacaine 0.625% with fentanyl 3 mcg/mL and 0.15% ropivacaine alone, there was no difference in pain relief; patient satisfaction was lower with PCEA ropivacaine, even though it led to fewer opioid-related adverse effects (Pitimana-aree 2005 **Level II**, n=70, JS 3).

No studies directly compare fentanyl to morphine when added to LA epidural infusions, although a single retrospective audit of the use of high-thoracic epidural following cardiac surgery suggested improved pain control and lowered infusion rate using ropivacaine 0.2% with

morphine 20 mcg/mL vs fentanyl 2 mcg/mL (Royse 2005 **Level III-3**, n=200). For information relating to the use of epidural LA or LA/opioid combinations for postoperative pain see Section 5.6.2 and for labour pain see Section 9.1.3.3.

4.4.2.4 | Peripheral local anaesthetics

A number of studies have compared different LAs or doses of LAs used for peripheral nerve block (PNB) and continuous peripheral nerve block (CPNB). Specific regional and local anaesthetic techniques are discussed in Section 5.8

In a meta-analysis comparing ropivacaine to levobupivacaine for peripheral nerve block, there was no difference in time to onset of anaesthesia or patient satisfaction, but levobupivacaine provides longer block (WMD -2.94 h; 95%CI -5.56 to -0.32) and a lower incidence of postoperative rescue analgesia (OR 2.11; 95%CI 1.18 to 3.74) (Li 2017a **Level I** [PRISMA], 12 RCTs, n=556); concentrations included ranged from 0.5% to 1.0% and non-equipotent comparisons were included.

At concentrations of 0.5% or greater, there were no significant differences in onset time and intensity or duration of sensory block between bupivacaine, levobupivacaine or ropivacaine in sciatic (Casati 2002 **Level II**, n=50, JS 4), interscalene (Casati 2003a **Level II**, n=47, JS 5) or axillary brachial plexus blocks (McGlade 1998 **Level II**, n=61, JS 5). In a comparison of three concentrations (0.1%, 0.2%, 0.3%) of ropivacaine for continuous FNB following TKA, infusions of 0.2% and 0.3% ropivacaine had equivalent quality of postoperative analgesia (Brodner 2007 **Level II**, n=102, JS 4). After similar surgery, there was no difference in pain relief or motor block between patient-controlled FNB with levobupivacaine 0.125% and ropivacaine 0.2% (Heid 2008 **Level II**, n=60, JS 4).

Comparisons of two different patient-controlled CPNB regimens found different results depending on the location of the block; the regimens were ropivacaine at 4 mL/h 0.4% (bolus 2 mL) or 8 mL/h 0.2% (bolus 4 mL). For continuous popliteal nerve block, the larger volumes of the dilute LA were more likely to cause an insensate limb (Ilfeld 2008 **Level II**, n=50, JS 3); for continuous interscalene nerve block there was no difference between the two solutions (Le 2008 **Level II**, n=50, JS 2) and for continuous infraclavicular nerve block the smaller volumes of the more concentrated LA were more likely to cause an insensate limb (Ilfeld 2009 **Level II**, n=50, JS 3).

In another RCT of patient-controlled continuous interscalene block comparing levobupivacaine 0.25%, ropivacaine 0.25% and ropivacaine 0.4%, the lower concentration of ropivacaine achieved less effective pain relief (Borghi 2006 **Level II**, n=72, JS 5).

Continuous popliteal sciatic nerve block using ropivacaine 0.2% vs levobupivacaine 0.2% and levobupivacaine 0.125% resulted in similar pain relief after foot surgery but fewer patients had complete recovery of motor function at 24 and 48 h with 0.2% levobupivacaine (Casati 2004 **Level II**, n=60, JS 5). Many continuous perineural infusion techniques now use low concentrations of ropivacaine (approx. 0.1%) in order to minimise motor block while still providing effective analgesia (see Section 5.8).

Skin infiltration

Increasing the pH of commercial lidocaine (to ≥7.35 by the addition of sodium bicarbonate prior to injection) reduces pain scores on injection for invasive procedures in cross-over studies (WMD -2/10; 95%CI -2.6 to -1.3) (10 RCTs) and in parallel design studies (WMD -1/10; 95%CI -1.4 to -0.4) (7 RCTs) (Cepeda 2010 **Level I** [Cochrane], 23 RCTs, n=1,067). The magnitude of the decrease in pain is larger when the solution contains adrenaline (WMD -2.5/10; 95%CI -3.2 to -1.7) (6 RCTs, n=232).

Warming the solution (to 37–43°C), assessed mostly in adults, reduces pain on SC or intradermal injection overall (WMD -11/100; 95%CI -14 to -7) (18 RCTs, n=831) and when the local anaesthetic is buffered (WMD -7/100; 95%CI -12 to -3) (8 RCTs, n=412) (Hogan 2011 **Level I** [PRISMA], 18 RCTs, n=831).

Local infiltration analgesia

Two main strategies using large volume, low concentration local anaesthetic infiltration techniques are described: tumescent local anaesthesia and local infiltration analgesia (LIA). Tumescent local anaesthesia has been described for soft-tissue surgery such as varicose vein sclerosis, liposuction or cosmetic breast surgery.

The term LIA typically refers to the systematic intraoperative injection of LAs in the periarticular and intra-articular regions. LIA may also be referred to as periarticular infiltration. A "cocktail" is most commonly used for periarticular LIA comprising a local anaesthetic, an alpha-2 agonist/vasoconstrictor, an opioid and an anti-inflammatory agent. The majority of investigations into the effectiveness of LIA in acute pain management following THA or TKA fail to separate out the components of the mixture and some protocols use "top-up" regimens of varying composition (Andersen 2014a **Level I** [PRISMA], 27 RCTs, n=1,644). In THA (n=756), multimodal systemic analgesia or neuraxial techniques (IT morphine or epidural analgesia) have similar analgesic efficacy vs LIA; however in TKA, LIA provided superior analgesia to placebo (n=328). Compared with FNB, epidural analgesia or IT morphine, LIA provided similar or improved analgesia in the early postoperative period, but most trials had a high risk of bias due to different systemic analgesia regimens between groups. Overall, the use of wound catheters for postoperative administration of local anaesthetic following LIA was not supported in the included trials.

Despite the many studies of LIA, final interpretation is hindered by methodological insufficiencies in most studies, especially because of differences in use of systemic analgesia between groups. For more detail see also Section 5.8.7.1.

There is limited data regarding local anaesthetic systemic toxicity (LAST) in patients receiving LIA with hip and knee joint surgery. In a case series of 39 patients receiving up to 300 mg ropivacaine as LIA, there was no clinical toxicity and peak plasma concentrations did not exceed 1.7 mcg/mL; peak concentrations occurred at ≈6 h post administration (Affas 2016 **Level IV**, n=39).

In volunteers receiving 41 exposures to tumescent subcutaneous infiltration of lidocaine with epinephrine, recommendations were made for up to 28 mg/kg lidocaine without liposuction and 45 mg/kg with liposuction with peak concentrations occurring 8–16 h after infiltration (Klein 2016 **Level IV EH**, n=14).

Slow-release preparations of local anaesthetics

Encapsulation of bupivacaine within liposomes in clusters of <100 microns diameter (liposomal bupivacaine) results in drug release into adjacent tissues for a number of days following injection, with peak plasma concentrations occurring 12–36 h after injection (Skolnik 2014 **NR**). Current indications from trial data have not raised any specific safety concerns (Viscusi 2014 **Level I**, 10 RCTs, n=823).

A limited number of RCTs have been conducted with wound infiltration, periarticular infiltration, perineural block and epidural administration (see Section 4.3.2.2 for ER epidural opioid preparations); most RCTs have demonstrated analgesic superiority over placebo for up to 72 h, however benefit over normal formulations of bupivacaine has not been shown (Tong 2014 **Level III-2 SR**, 5 studies, n unspecified). When comparing wound infiltration with liposomal bupivacaine to either ropivacaine or plain bupivacaine, no difference was seen with analgesic outcomes up to 48 h (Kendall 2018 **Level I** [PRISMA], 9 RCTs, n=779).

A systematic review of liposomal bupivacaine for periarticular infiltration in TKA (Yayac 2019 **Level IV SR** [PRISMA], 6 SRs & 17 RCTs & 25 studies, n unspecified) finds:

- vs conventional LA single injection PNB (3 RCTs, n=555), pain relief is better with PNB (SMD 0.45, 95%CI 0.08 to 0.82), largely driven by benefits on POD 0 and 1; there is no

difference in opioid consumption. Differences in complication rates, including falls, are mixed;

- vs conventional LA LIA (13 RCTs, n=1,155), slightly lower pain scores are found using AUC over 5 d (SMD = -0.08, 95%CI -0.14 to -0.03), but not using pain scores by time-point up to 3 d (-5.21/100; 95%CI -12.1 to 1.65). There are no differences in opioid consumption nor functional recovery;
- vs conventional LA IA infiltration (2 RCTs, n=345), only one study included a direct comparison and found no difference in pain outcomes.

Also in TKA, two overlapping meta-analyses compared liposomal bupivacaine by periarticular infiltration to conventional LA FNB (Liu 2017a **Level III-2 SR** [PRISMA], 1 RCT & 7 studies, n=2,407; Ma 2016b **Level III-2 SR**, 1 RCT & 5 studies, n=1,289) (all 6 studies overlap); 2 FNB studies used continuous infusions. There is no difference between groups in pain scores to 72 h, PONV or range of motion, but liposomal bupivacaine is associated with decreased LOS (MD -0.43 d; 95%CI -0.60 to -0.27) and reduced total morphine requirements (MD -29.3 mg; 95% CI -57.6 to -1.1) (Liu 2017a **Level III-2 [PRISMA]**, 1 RCT & 7 studies, n=2,407).

In THA, LIA with liposomal bupivacaine vs conventional bupivacaine showed no difference up to 72 h in postoperative opioid consumption, pain scores, opioid-related side effects, time to first ambulation, or LOS (Perets 2018 **Level II**, n=107, JS 4).

Following day-case retropubic sling placement, pain scores were low but liposomal bupivacaine infiltration vs saline improved scores slightly at 4 h post-discharge and the following morning (Mazloomdoost 2017 **Level II**, n=109, JS 4).

4.4.3 | Local anaesthetic toxicity

4.4.3.1 | Direct toxicity

Nerve injury following perineural LA injection may be a consequence of many factors including needle trauma, haematoma, pressure injury, or direct local anaesthetic toxicity (Verlinde 2016 **NR**). In clinical practice it is difficult, if not impossible to separate out these elements, and the likely contribution of direct neurotoxicity is small. All local anaesthetics exhibit neurotoxicity if nerves are exposed to sufficiently high concentrations for a sufficiently long period (Verlinde 2016 **NR BS**). Lidocaine 5% infused via lumbar subarachnoid microcatheters has been associated with case reports of cauda equina syndrome (Rigler 1991 **Level IV**, n=4; Schell 1991 **Level IV**, n=2). This suggested that high local concentrations of lidocaine were potentially neurotoxic and led to the technique falling into disfavour. The precise mechanisms of direct LA neurotoxicity remain unclear, but are concentration-dependent, and may involve the intrinsic caspase-pathway, PI3k-pathway, and MAPK-pathways (Verlinde 2016 **NR BS**).

Transient neurological symptoms (TNS) is a clinical syndrome associated with spinal (IT) anaesthesia. Patients experience pain or muscle spasms in the buttocks or lower limbs following initial recovery from the spinal anaesthetic. The onset of symptoms is usually within 24 h of the procedure and it fully resolves spontaneously within a few days. Despite its name, there is no evidence that this condition is associated with actual neurologic pathology. A network meta-analysis showed that the risk of TNS was lower for bupivacaine, levobupivacaine, prilocaine, procaine, and ropivacaine with RRs in the range of 0.10 to 0.23 vs lidocaine; while 2-chloroprocaine and mepivacaine did not differ to lidocaine (Forget 2019 **Level I** [Cochrane] [NMA], 24 RCTs, n=2,226). The quality of evidence was considered moderate to low, and the overall incidence of TNS was 10.7%.

Other tissues are susceptible to direct toxicity from local anaesthetics. Myotoxicity has been described clinically (Zink 2004 **NR**) and reproduced experimentally (Yildiz 2011 **BS**), especially for bupivacaine, but is rare and reversible. Local anaesthetics have chondrotoxic effects on articular cartilage, which are worsened by coadministration of corticosteroids (Jayaram 2019 **Level III-2 BS** [PRISMA], 16 studies, n unspecified); ropivacaine at concentrations of 0.5% or less was found to be the least chondrotoxic LA.

4.4.3.2 | Local anaesthetic systemic toxicity (LAST)

There is consistent laboratory data showing that the S-enantiomers of the long-acting amide LAs exhibit less CNS or cardiac toxicity than the R-enantiomers or the racemic mixtures for doses resulting in equivalent sensory nerve conduction block. Defining relative toxicities for these agents is complex because it depends on the parameters measured (eg cardiac, CNS), the dose, route and species studied. There is lack of scientific data available to determine a safe maximal dose of local anaesthetic. However, the upper limit of a dose should take into account patient weight, age and comorbidities. There is a pharmacokinetic rationale to support fractional dosing by incremental injection of local anaesthetic in addition to identifying unintended intravascular injection.

The incidence of local anaesthetic systemic toxicity (LAST) has been quantified using registry databases at 0.03% or 0.27/1,000 PNBs (95%CI 0.21 to 0.35) (Gitman 2018 **Level IV**, n=251,325). Factors associated with increased LAST events were paravertebral (OR 9.20; 95%CI 2.24 to 37.8) and upper limb blocks (OR 4.80; 95%CI 1.23 to 18.7), the use of lidocaine vs ropivacaine (OR 5.64; 95%CI 2.02 to 15.7) and larger doses of local anaesthetic (Barrington 2013 **Level IV**, n=25,336 [PNBs in n=20,021 patients]).

The use of ultrasound and LAST

The use of ultrasound (US) was associated with a reduced incidence of LAST (OR 0.23; 95%CI 0.088 to 0.59) (Barrington 2013 **Level IV**, n=25,336 [PNBs] in n=20,021 [patients]); this may be due to increased precision of needle placement with US guidance (minimising intravascular placement) (Neal 2016 **Level IV SR**, 27 studies, n=1,867), or the use of lower doses of local anaesthetic. A meta-analysis identifies a significantly decreased risk of vascular puncture using US (RR 0.16; 95%CI 0.05 to 0.47) (Abrahams 2008 **Level I**, 13 RCTs, n=946). These data form the basis for the current Class I-B ASRA recommendations for the use of US to reduce LAST (Neal 2018 **GL**). It should be noted that LAST episodes continue to occur despite precautionary measures, including US use (Gitman 2018 **Level IV SR**, n=47 [episodes of LAST]).

Seizures related to LAST

The most common presenting feature of LAST was seizure (53% and 61%; from case reports and registries respectively) (Gitman 2018 **Level IV**, n=251,325). In blinded human-volunteer studies, CNS symptoms were detected at IV doses and plasma concentrations that were 25% higher for ropivacaine vs bupivacaine (Scott 1989 **Level II EH,** n=12, JS 2) and 16% higher for levobupivacaine than bupivacaine (Bardsley 1998 **Level II EH**, n=14, JS 3). Although these data show that CNS toxicity might occur less frequently or be less severe with the S-enantiomers, all local anaesthetics are toxic. A rapid IV bolus of any of these agents may overwhelm any of the more subtle differences found at lower plasma concentrations.

Cardiac events related to LAST

Severe myocardial depression and refractory ventricular fibrillation have been described as the hallmark of accidental IV administration of moderately large doses of bupivacaine. This has been attributed to the slow dissociation of bupivacaine from the myocardial sodium channel, which is less marked with levobupivacaine and ropivacaine (Mather 2001 **NR**). Animal studies confirm that

higher systemic doses of ropivacaine and levobupivacaine are required to induce ventricular arrhythmias, circulatory collapse or asystole (Ohmura 2001 **BS**), with the ranking of toxicity risk being bupivacaine > levobupivacaine > ropivacaine (Groban 2001 **NR**).

Controlled human studies are only possible when looking at surrogate endpoints such as ECG changes or myocardial depression and suggest a similar ranking of adverse effects (Bardsley 1998 **Level II EH**, n=14, JS 5; Knudsen 1997 **Level II EH**, n=12, JS 5; Scott 1989 **Level II EH**, n=12, JS 5), with bupivacaine being the most toxic and levobupivacaine being less toxic and similar to ropivacaine (Stewart 2003 **Level II EH**, n=14, JS 5).

Successful resuscitation from a massive overdose is of greater relevance in clinical practice. A canine study investigating resuscitation (not using lipid emulsion) and survival following local anaesthetic-induced circulatory collapse showed survival rates of 50%, 70% and 90% with bupivacaine, levobupivacaine and ropivacaine respectively (Groban 2001 **BS**).

Case reports of accidental toxic overdose with ropivacaine suggest that outcomes are more favourable and resuscitation more straightforward (in particular requiring less cardiovascular support) than with racemic bupivacaine (Weiss 2014 **CR**; Hubler 2010 **CR**; Kimura 2007 **CR**; Khoo 2006 **CR**; Soltesz 2003 **CR**; Chazalon 2003 **CR**; Huet 2003 **CR**; Klein 2003 **CR**; Pham-Dang 2000 **CR**). This data is prior to the widespread use of guidelines and lipid emulsion therapy, and a review of case-series and registry data over 33 mth from March 2014 identified only 2 reported deaths out of 47 events, one case having delayed therapy and the other related to lidocaine (Gitman 2018 **Level IV SR,** n=47 [episodes of LAST]).

Total plasma concentrations of LAs tend to rise during the first 48 h of postoperative infusion, although free levels remain relatively low (Scott 1997 **Level IV**, n=11; Emanuelsson 1995 **EH PK**). Thus, in published studies, toxicity due to systemic absorption from epidural or perineural infusions has not been a problem. However, the risk of accidental absolute overdose with postoperative infusions and the increasing use of fascial plane infusions, suggests that the less toxic agents should be used in preference and that the doses administered should be the minimum needed for efficacy.

Lipid emulsion therapy

Lipid emulsion therapy is advocated for in the treatment of LAST (Neal 2018 **GL**; AAGBI 2010 **GL**). Animal experimental data (Weinberg 2003 **BS**; Weinberg 1998 **BS**) has been supported by case reports of successful resuscitation following bupivacaine (Rosenblatt 2006 **CR**), ropivacaine (Litz 2006 **CR**), levobupivacaine (Foxall 2007 **CR**), mepivacaine/prilocaine (Litz 2008 **CR**) and mepivacaine/bupivacaine (Warren 2008 **CR**) toxicity and published case series of use of IV lipid emulsion therapy (Gitman 2018 **Level IV SR**, n=47 [LAST episodes]; Cave 2014 **Level IV**, n=10 (LAST episodes]; Felice 2008 **Level IV**, n=4).

The mechanism of action of the lipid emulsion may be due to partitioning of local anaesthetic within the emulsion itself (acting as a “lipid sink” or “shuttling”) (Fettiplace 2018 **NR**), mitochondrial substrate enhancement in the myocardium (Weinberg 2000 **BS**) and/or a direct inotropic effect (Fettiplace 2014 **BS**). Uncertainties relating to dosage, efficacy and adverse effects (Cave 2014 **Level IV**, n=10 (LAST episodes]) still remain, however, lipid administration appears safe. The ASRA Practice Advisory on Local Anesthetic Systemic Toxicity recommends the administration of IV lipid emulsion therapy at the first signs of LAST but following airway management (Class I-B recommendation) (Neal 2018 **GL**). In suspected LAST, it is also recommended to administer lipid emulsion immediately after airway support has commenced and ventilation is controlled (convulsions may or may not need control at this point in order to ventilate) (Neal 2018 **GL**); this prevents hypoxia, hypercapnia, and acidosis which are known to potentiate LAST. It should be noted that local anaesthetic toxicity might recur following

successful initial resuscitation, suggesting a need for continued intensive observation if a large dose of local anaesthetic has been administered (Marwick 2009 **GL**).

The ASRA guidelines are also available as an app for mobile phones and tablets ('*ASRA LAST*') (Neal 2018 **GL**).

LAST is also discussed in Section 5.8.11.3 and in paediatric patients in Section 10.6.3.5 (including adverse effects of lipid emulsion use).

KEY MESSAGES

1. Lidocaine intrathecal is more likely to cause transient neurologic symptoms than bupivacaine, prilocaine and procaine (**S**) (**Level I** [Cochrane Review NMA]).
2. Local anaesthetics have chondrotoxic effects on articular cartilage, with ropivacaine the least toxic (**N**) (**Level I** [PRISMA]).
3. Wound infiltration with liposomal preparations of bupivacaine is no more effective than ropivacaine or plain bupivacaine for analgesic outcomes up to 48 hours (**N**) (**Level I** [PRISMA]).
4. The quality of epidural analgesia with local anaesthetics is improved with the addition of opioids (**U**) (**Level I**).
5. Ultrasound guidance reduces the risk of vascular puncture during the performance of regional blocks (**S**) (**Level I**).
6. Local anaesthetic systemic toxicity is reduced by the use of ultrasound guidance for regional anaesthesia (**S**) (**Level I**).
7. Continuous perineural infusions of lidocaine result in less effective analgesia and more motor block than long-acting local anaesthetic agents (**U**) (**Level II**).
8. There are no consistent differences between ropivacaine, levobupivacaine and bupivacaine in terms of quality of analgesia or motor block, when given in low doses for regional analgesia (epidural and peripheral nerve block) (**U**) (**Level II**).
9. Cardiovascular and central nervous system toxicity of the stereospecific isomers ropivacaine and levobupivacaine is less severe than with racemic bupivacaine (**U**) (**Level II**).
10. Local anaesthetic systemic toxicity is increased in paravertebral and upper limb blocks, with the use of lidocaine and higher doses of local anaesthetics (**U**) (**Level IV**).
11. Lipid emulsion is effective in resuscitation of circulatory collapse due to local anaesthetic toxicity (**S**) (**Level IV SR**); however, uncertainties relating to dosage, efficacy and adverse effects still remain; therefore, it is appropriate to administer lipid emulsion only once ventilatory support has begun and convulsions are controlled (**S**) (**Level IV**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Case reports following accidental overdose with ropivacaine, levobupivacaine and bupivacaine suggest that resuscitation is less likely to be successful with bupivacaine (**U**).

4.5 | Inhalational agents

4.5.1 | Nitrous oxide

N_2O has been used since the inception of anaesthesia for its modest analgesic and sedative properties. It has minimal respiratory and cardiovascular depression. In many countries it is available as a 50% N_2O /50% oxygen mixture called Entonox®. While it has a long history of use, there is a paucity of good studies examining its effectiveness in comparison with other analgesics (Buhre 2019 **NR**).

In a meta-analysis of inhaled analgesics in labour, subgroup analysis of N_2O shows minimal analgesic difference vs placebo (RR 0.06; 95%CI 0.01 to 0.34) (MD 3.5/100; 95%CI -3.75 to -3.25) (Klomp 2012 (**Level I** [Cochrane], 3 RCTs [N_2O], n=819). A systematic review shows that N_2O in oxygen has some analgesic efficacy in labour (Likis 2014 **Level IV SR**, 58 studies, n=20,266). Only two studies were of good quality. N_2O provides less analgesia than epidural analgesia but more than pethidine, or bath and shower. Maternal satisfaction with the birth experience using N_2O for analgesia is higher than for pethidine or epidural analgesia. The reports of maternal adverse effects in this review are nausea, vomiting, dizziness and drowsiness. Apgar scores are no different for N_2O vs no analgesia. A subsequent systematic review vs multiple comparators, was overall of low quality and did not add to the previous information (Sheyklo 2017 **Level I** [PRISMA], 14 RCTs, n=2,158) (See also Section 9.1.3.2).

N_2O was effective during painful procedures such as venous cannulation (Gerhardt 2001 **Level II**, n=10, JS 5), sigmoidoscopy (Harding 2000 **Level II**, n=77, JS 5), dermatological procedures (Brotzman 2018 **Level IV SR**, 8 studies, n=438), extraction of gauze packing strips after Caldwell-Luc operation (Dong 2017 **Level II**, n=47, JS 4), lumbar puncture (Moisset 2017 **Level II**, n=66, JS 5), transrectal prostate biopsy (Cazarim 2018 **Level II**, n=84, JS 4), liver biopsy (Castera 2001 **Level II**, n=100, JS 5), in relieving acute ischaemic chest pain (O'Leary 1987 **Level II**, n=12, JS 2) and in trauma patients in the prehospital setting (Ducasse 2013 **Level II,** n=60, JS 4). In elderly patients (median age 84 y), N_2O provided better analgesia than morphine during bed sore and ulcer care (Paris 2008b **Level II**, n=34, JS 3). For colonoscopy, there was no difference in pain intensity between continuous and as-required 50% N_2O use (Ball 2015 **Level II**, n=108, JS 5).

While a previous study reported benefits in bone marrow aspiration (Gudgin 2008 **Level III-3**, n=16), a subsequent RCT found no difference in pain and anxiety scores between 50% N_2O in oxygen and an oxygen/air mixture (Kuivalainen 2015 **Level II**, n=60, JS 3). Similarly, for intrauterine device insertion, there was no analgesic effect of 50% N_2O vs oxygen (Singh 2016b **Level II**, n=80, JS 5) and there was no pain relieving or opioid-sparing effect of 65% N_2O vs oxygen for burns dressing changes (do Vale 2016 **Level III-1**, n=15).

For lower gastrointestinal endoscopy, there is no difference in pain scores between N_2O and IV opioid/midazolam, or the ability to successfully complete the procedure (Welchman 2010, **Level I**, 11 RCTs, n=623). The N_2O group has a shorter time to achieve fitness for discharge. Self-administration of 50% N_2O combined with PO morphine vs the same dose of PO morphine alone resulted in better pain control of breakthrough pain in cancer patients at 5 and 15 min (Liu 2018 **Level II**, n=240, JS 5).

As no RCTs compare N_2O and methoxyflurane, an indirect comparison for pain relief in the ED showed no significant differences in efficacy between the two agents (Porter 2018b **Level I** [NMA], 2 RCTs, n=263).

For use in paediatrics see Section 10.7.2 and 10.7.4.

In an experimental setting, a study measuring changes in detection and pain thresholds to electrical tooth stimulation reported the development of acute and chronic tolerance in

response to single and repeated administration of N_2O (38% or 35%) for 30 min (Ramsay 2005 **EH**). The significance of this finding in the clinical setting is unknown.

A *post-hoc* analysis of an RCT (ENIGMA) using telephone interviews at a median of 4.5 y following (mostly abdominal) surgery found that the intraoperative use of N_2O reduced the risk of chronic postsurgical pain in an Asian population (OR 0.48; 95%CI 0.33 to 0.93) (Chan 2011 **Level II**, n=423, JS 5); factors increasing risk included severity of acute postoperative pain, wound length, wound infection and anxiety. These findings were confirmed in a planned subgroup analysis in Asian vs non-Asian patients (RR 0.70; 95%CI 0.50 to 0.98) of a subsequent RCT (ENIGMA II) (Chan 2016 **Level II**, n=2,924 [phone interviews at 12 mth postop], JS 5).

N_2O attenuated remifentanil induced tolerance/hyperalgesia (Wehrfritz 2016 **Level II EH**, n=21, JS 5; Echevarria 2011 **Level II**, n=50, JS 4).

N_2O diffuses more rapidly than nitrogen and can expand enclosed air-containing spaces within the body. Its use is therefore contraindicated in the presence of a pneumothorax, obstruction of middle ear and sinus cavities, recent vitreoretinal surgery, pneumocephalus, bowel obstruction and gas embolism (Shaw 1998 **NR**).

4.5.1.1 | Toxicity

N_2O oxidises the cobalt ion of cobalamin (vitamin B_{12}) preventing it from acting as a coenzyme for methionine synthetase; methionine synthetase also requires 5-methyltetrahydrofolate as a coenzyme (Sanders 2008 **NR**). Methionine synthetase is required for the synthesis of deoxyribonucleic acid and ribonucleic acid and therefore the production of cells in rapidly dividing tissues such as bone marrow and gastrointestinal mucosa, as well as the synthesis of myelin (Sanders 2008 **NR**). Exposure of young children (median age 11 mth) to N_2O anaesthesia for more than 2 h leads to a statistically significant but small increase in total homocysteine plasma concentrations on the first postoperative morning with unclear clinical relevance (Pichardo 2012 **Level IV**, n=32).

Bone marrow and neurological complications have been reported in patients exposed to N_2O. A systematic review identified 100 cases of neurological toxicity, of which 57% resulted from recreational use (Oussalah 2019 **Level IV SR**, 85 studies, n=100 [cases]). Other reasons for exposure were surgery in 25%, occupational exposure in 9%, pain control in 6% and procedural sedation in 1%. Clinical symptoms included paraesthesia in 80%, unsteady gait in 58% and weakness in 43%. The most common diagnoses were subacute combined degeneration (SACD) of the spinal cord in 28%, myelopathy in 26% and generalized demyelinating polyneuropathy in 23%; a T2 signal hyperintensity in the MRI of the spinal cord was seen in 68%. Pathological haematological findings occurred in 72%. The most relevant factor was possible or probable vitamin B_{12} deficiency (diagnosed on the combined indicator of vitamin B_{12} status [cB_{12}] scoring system [Fedosov 2015 **BS**]) in 85%. In a univariate risk analysis, the following risk factors were identified: age ≥40 y (OR 23.3; 95%CI 6.8 to 79.6), vitamin B_{12} level ≤74 pmol/L (OR 6.06; 95%CI 2.05 to 17.9) and MCV >100 fL (OR 9.8; 95%CI 1.9 to 49.1). The dose of N_2O was not associated with any outcome.

A parallel systematic review of SACD excluded recreational users (Patel 2018 **Level IV SR**, 32 studies, n=39 [cases]) (significant overlap). Again in 84% of cases vitamin B_{12} malabsorption secondary to a gastrointestinal disorder was the underlying causation. Classical symptoms were proprioceptive and vibratory sensation loss in 67% and burning or tingling paraesthesia in 59%. Again, there was no association to exposure duration. Most notably, supplementation with vitamin B_{12} resulted in complete recovery in 33% and partial improvement in 64%. Mean time to complete resolution was 37 wk (4 wk to 3 y).

The risk may be greater in critically ill patients with increased metabolic demands or poor nutrition (Amos 1982 **Level IV**, n=70). N_2O-induced bone marrow toxicity leading to megaloblastic anaemia is usually progressive but reversible. The bone marrow changes were almost completely prevented by administration of folinic acid (Amos 1982 **Level IV**, n=70).

The following case reports are included in the systematic reviews above, but highlight specific risk factors: those at risk of vitamin B_{12} deficiency include some vegetarians (in particular vegans) (Rosener 1996 **CR**), the newborns of vegetarian mothers (McNeely 2000 **CR**), patients with gastrointestinal pathology (Schilling 1986 **Level IV**) or phenylketonuria (Walter 2011 **NR**), being elderly (Nilsson-Ehle 1998 **NR**), patients taking PPIs (Schenk 1999 **Level IV**) or H2 blockers and alcoholics (Sanders 2008 **NR**; Carmel 2000 **NR**). Cases have also been reported in those abusing the drug (eg obtained from whipped cream chargers) or being exposed to N_2O for medical purposes after longer periods of abuse (Lin 2011 **Level IV**, n=3; Rheinboldt 2014 **CR**; Hu 2014 **CR**; Chiang 2013 **CR**; Cheng 2013 **CR**; Ghobrial 2012 **CR**; Sanders 2008 **NR**).

The neuropathy appears to be the result of decreased methionine and subsequent defective myelin formation. Involvement of peripheral, autonomic and central nervous systems may also lead to incontinence, diplopia, confusion or impaired cognitive function (Weimann 2003 **NR**). Despite the lack of any good data assessing efficacy in humans, and even though the bone marrow changes are usually reversible, it may be reasonable to give patients repeatedly exposed to N_2O, vitamin B_{12} and folic or folinic acid supplements (Weimann 2003 **NR**).

Another consequence of N_2O-induced inactivation of methionine synthetase is elevation of plasma homocysteine (a known risk factor for coronary artery and cerebrovascular disease), the levels of which rise after anaesthesia using N_2O (Myles 2008 **Level II**, n=59, JS 3; Badner 1998 **Level II**, n=20, JS 2; Nagele 2008 **Level III-3**, n=140). Patients who are homozygous for polymorphisms in the gene encoding the enzyme that is an antecedent to methionine synthetase are at a higher risk of developing abnormal plasma homocysteine concentrations after N_2O anaesthesia (Nagele 2008 **Level III-3**, n=140). However, the large ENIGMA II study, comparing oxygen 30% with or without N_2O (70%) in patients with known or risk factors for ischaemic heart disease, found no difference in serious adverse effects in the N_2O group vs the non-N_2O group (Myles 2014 **Level II**, n=7,112, JS 3). However, as this study examined patients who were undergoing major surgery that lasted for at least 2 h, the applicability to the setting of analgesia may be limited.

Methionine given preoperatively to patients undergoing N_2O anaesthesia improved the rate of recovery of methionine synthetase and prevented the prolonged postoperative rise in plasma homocysteine concentrations (Christensen 1994 **Level IV**, n=14). Preoperative administration of oral B vitamins (folate, B_6 and B_{12}) (Badner 2001 **Level II**, n=53, JS 3) and of vitamin B_{12} infusions (Kiasari 2014 **Level II**, n=60, JS 5) also prevented the postoperative increase in homocysteine following N_2O anaesthesia.

The information about the complications of N_2O derives from case reports only. There are no controlled studies that evaluate the safety of repeated intermittent exposure to N_2O in humans and no data to guide the appropriate maximum duration or number of times a patient can safely be exposed to N_2O. Nevertheless, the potential problems require highlighting. The suggestions for the use of N_2O outlined below are extrapolations only from the information above.

4.5.1.2 | Suggestions for the use of nitrous oxide as an analgesic

When N_2O is to be used repeatedly for painful short procedures, it may be reasonable to:

- Exclude patients with persistent vitamin B_{12} deficiency;
- Screen patients at risk of vitamin B_{12} deficiency by examination of the blood picture and serum B_{12} concentrations before using N_2O repeatedly;

- Exclude asymptomatic patients with macrocytic anaemia or hypersegmentation of neutrophils until it is established that vitamin B_{12} or folate deficiency is not the cause;
- Exclude females who may be in the early stages of pregnancy, although this will depend on the relative harm of any alternative methods;
- Limit exposure to N_2O to the briefest possible time — restricting the duration of exposure may require strict supervision and limited access to the gas;
- Administer methionine, vitamin B_{12} (both with a good safety profile) and possibly folic or folinic acid to patients repeatedly exposed to N_2O (doses that may prevent the complications of exposure to N_2O have not been established);
- Monitor for clinical signs and symptoms of neuropathy on a regular basis and start treatment with vitamin B_{12} early.

4.5.2 | Methoxyflurane

Methoxyflurane is a volatile anaesthetic agent with analgesic properties. It was first marketed in 1962 and later withdrawn from sale in 2001. The FDA withdrew the medicine because of the risk of nephrotoxicity and hepatotoxicity and stated that it would not consider reintroduction into the market until new clinical trials were undertaken (FDA 2005). Methoxyflurane is no longer licensed for anaesthesia in humans.

Although no longer used as an anaesthetic, methoxyflurane has been registered in Australia and New Zealand (as well as now a number of other countries) for use as an analgesic in low doses since 1975 for relief of trauma-associated acute pain as well as procedural pain (Porter 2018a **NR**; Jephcott 2018 **NR**; Medical Devices International 2009). It is available as a self-administered "Penthrox®" inhaler, which dispenses 0.2 to 0.4% methoxyflurane (Medical Devices International 2009).

As an analgesic in prehospital and ED settings, methoxyflurane has been reported as effective (Yeung 2018 **Level III-2 SR** [PRISMA], 2 SRs & 2 studies, n>43,823 [methoxyflurane recipients]; Grindlay 2009 **Level IV SR,** 6 studies [analgesia], n=293). Methoxyflurane provided inferior analgesia to IV morphine and IN fentanyl in the prehospital setting with minimal adverse effects (1 study, n=42,844) (Yeung 2018 **Level III-2 SR**, 2 SRs & 2 studies, total n unspecified). In ED patients aged ≥12 y, it was significantly more analgesic than placebo, with only mild transient adverse effects such as dizziness and headache (Wells 2018 **Level I** [PRISMA, 1 RCT: Coffey 2014 **Level II**, n=300, JS 4). The median time to onset of analgesia was rapid at 4 min and time to peak analgesia was 15 min. Safety was assessed over 14 d following administration and no significant adverse effects were found, including no renal impairment. Use of the Penthrox® inhaler in children reduced pain associated with extremity injuries (Babl 2006 **Level IV**, n=15) but did not provide adequate analgesia for subsequent fracture manipulation (Babl 2007 **Level IV**, n=14). It also provided effective pain relief for adult patients in the prehospital setting, as shown in adults travelling by ambulance to an urban teaching hospital (Buntine 2007 **Level IV**, n=83). Adverse effects included hallucinations, vomiting, confusion and dizziness, and sedation/drowsiness was common (26%) in children (Buntine 2007 **Level IV**, n=83; Babl 2006 **Level IV**, n=15).

As an analgesic for painful procedures outside of the ED, methoxyflurane was first described for obstetric analgesia in 1966 (Bodley 1966 **Level IV**, n=62) and then used as an analgesic for burns dressing (Marshall 1972 **Level IV**, n=60 [procedures in 10 patients]; Firn 1972 **Level IV**, n=94 [procedures in 36 children]; Packer 1969 **Level IV**, n=60 [procedures in 11 patients]). Methoxyflurane was effective for prostate biopsies achieving a low pain score (median 3/10), mild adverse effects and high patient acceptance (Grummet 2012 **Level IV**, n=42). However, methoxyflurane combined with periprostatic infiltration of local analgesia provided superior analgesia vs methoxyflurane alone (Huang 2016 **Level III-1**, n=72). In patients having colonoscopies, methoxyflurane vs IV

fentanyl/midazolam resulted in similar pain scores but shorter recovery and fitness for discharge times, no respiratory depression, and high degree of patient satisfaction (Nguyen 2013 **Level II** n=250, JS 3). Ten patients in the methoxyflurane group required supplementation with IV sedation.

In patients having bone-marrow biopsies, local anaesthetic infiltration plus methoxyflurane vs placebo inhaler resulted in lower worst pain scores (4.9 vs 6.0/10) (Spruyt 2014 **Level II**, n=97, JS 4). Adverse effects were mild and of short duration. The overall efficacy was also confirmed in an audit of methoxyflurane use for procedural analgesia in a variety of procedures with reported success in 97% and minimal adverse effects (Gaskell 2016a **Level IV**, n=173 [procedures in 123 patients]).

As no RCTs compare methoxyflurane and N_2O, an indirect comparison for pain relief in the ED showed no significant differences in efficacy between the two agents (Porter 2018b **Level I** [NMA], 2 RCTs, n=263). In an unblinded comparison between self-administered methoxyflurane and IV PCA ketamine/midazolam for burns dressing both achieved similar analgesia with patient preference for methoxyflurane (Gaskell 2016a **Level II**, n= 8 [cross over], JS 3).

4.5.2.1 | Toxicity

Methoxyflurane causes dose-dependent renal toxicity and, as noted above, renal failure was a key reason behind the withdrawal of the medicine from use. Use of an analgesic device delivering higher concentrations of methoxyflurane was reported to have led to two fatalities from renal toxicity (Toomath 1987 **Level IV**). However, the amount of methoxyflurane delivered using the Penthrox® inhaler is said to be significantly less than the dose that has been associated with subclinical nephrotoxicity (Grindlay 2009 **NR**). There have been no reports of toxicity (Grindlay 2009 **NR**) with dosing limited to 6 mL/d or 15 mL/wk (Medical Devices International 2009). A large population database study found no long-term (up to 14 y) adverse effects (heart disease, renal disease, hepatic disease, diabetes, or cancer) in patients who had been given methoxyflurane by an ambulance service (Jacobs 2010 **Level IV**; n=17,629). The maximum dose approved (6 mL/d and 15 mL/wk) is calculated to achieve a minimum alveolar concentration (MAC) of 0.59 MAC-h (Dayan 2016 **NR**). Methoxyflurane ≤2.0 MAC-h results in serum fluoride ≤40 micmol/L, which has not been associated with renal tubular toxicity, thereby suggesting a safety margin of at least 2.7 to 8-fold of the approved dose limits.

There has been one documented case report of acute hepatitis following three administrations of methoxyflurane in an otherwise healthy woman for procedural analgesia (O'Rourke 2011 **CR**).

Methoxyflurane is contraindicated in patients with known or at genetic risk of malignant hyperpyrexia as well as in patients with renal impairment (Medical Devices International 2009).

KEY MESSAGES

1. Nitrous oxide has some analgesic efficacy in labour pain (**U**), increases maternal adverse effects (nausea, vomiting, dizziness) (**U**), with no adverse effects on the newborn (**U**) (**Level I** [Cochrane Review]) and increases maternal satisfaction compared to pethidine and epidural analgesia (**U**) (**Level IV SR**).
2. Nitrous oxide has equivalent effectiveness and more rapid recovery compared with intravenous sedation in patients having lower gastrointestinal endoscopy (**U**) (**Level I**).
3. Methoxyflurane, in low doses, is an effective analgesic with rapid onset in the prehospital setting, and a range of procedures in the hospital setting (**U**) (**Level II**) with good safety data (**S**) (**Level IV**); it may have comparable efficacy to nitrous oxide (**N**) (**Level I** [NMA]), but is inferior to IV morphine and IN fentanyl (**N**) (**Level III-2 SR**).
4. Nitrous oxide is an effective analgesic agent in a variety of other acute pain situations (**U**) (**Level II**).
5. Intraoperative use of nitrous oxide reduces the incidence of chronic postsurgical pain in Asian populations (**N**) (**Level II**).
6. Subacute combined degeneration of the spinal cord, myelopathy and generalised demyelinating polyneuropathy are rare but potentially serious complications of nitrous oxide use including in those abusing nitrous oxide (**S**) (**Level IV SR**).
7. Vitamin B_{12} deficiency (identified by vitamin B_{12} level $\leq$74 pmol/L and MCV >100 fL) and age $\geq$40 years are relevant risk factors in nitrous oxide neurotoxicity; total nitrous oxide exposure may not be a risk factor (**N**) (**Level IV SR**).
8. Early supplementation with Vitamin B_{12} in subacute combined degeneration of the spinal cord exacerbated by nitrous oxide use improves neurological recovery (**N**) (**Level IV SR**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ In patients receiving nitrous oxide repeatedly, supplementation with vitamin B_{12}, methionine and folic or folinic acid is a consideration, in particular in those with risk factors (**Q**).

☑ If nitrous oxide is used with other sedative or analgesic agents, appropriate clinical monitoring should be used (**U**).

4.6 | NMDA-receptor antagonists

NMDA-receptor/ion-channel complexes are located peripherally and centrally within the nervous system (Gonda 2012 **NR**). These ionotropic receptors are an important component of glutamergic neurotransmission and thereby involved in multiple functions within the nervous system including learning and memory, cognitive functions, neural development, neuroplasticity, excitotoxicity, addiction, psychiatric disorders and nociception (Li 2016a **NR**).

At the spinal level, NMDA-receptor activation results in the development of central sensitisation manifested clinically as hyperalgesia and allodynia (Petrenko 2014 **NR**; Hocking 2007 **NR**). Activation of NMDA receptors via glutamate release from excitatory synapses augments the propagation of nociceptive information and is therefore linked to acute and chronic pain states as well as opioid-induced tolerance and hyperalgesia.

The NMDA-receptor antagonists ketamine, dextromethorphan, amantadine, memantine and magnesium have been investigated for the management of acute pain (Kreutzwiser 2019 **NR**; Jonkman 2017 **NR**).

4.6.1 | Systemic NMDA-receptor antagonists

4.6.1.1 | Ketamine

In low (subanaesthetic) doses, ketamine acts primarily as a noncompetitive antagonist of the NMDA receptor, although it also binds to many other sites in the peripheral and central nervous systems (Petrenko 2014 **NR**; Sleigh 2014 **NR**; Mion 2013 **NR**). In more detail it is a "high-trapping" antagonist with a slow off-rate, causing a prolonged tonic block; therefore it has higher adverse effect rates than "low-trapping" antagonists with a fast off-rate such as memantine (Sleigh 2014 **NR**). Consequently, ketamine's main role is as an adjuvant in the treatment of pain associated with central sensitisation (Persson 2013 **NR**), such as in severe acute pain, neuropathic pain (Zhou 2011 **NR**) (see Section 8.1.4) and "opioid-resistant" pain (Kreutzwiser 2019 **NR**; Tawfic 2013 **NR**). See also Section 9.7 and for paediatric use Section 10.4.7.

In experimental pain, low-dose ketamine (<1 mg/kg) reduces the area of hyperalgesia (SMD 0.54; 95% CI 0.34 to 0.74) and pain intensity (MD -1.2/10; 95%CI -0.88 to -1.44) (54 RCTs [ketamine]: 43 RCTs [IV administration]) (Thompson 2019 **Level I EH** (PRISMA), 70 RCTs, n=1,069).

In Australia and New Zealand, ketamine is supplied as a racemic mixture (S- and R- enantiomers), although a number of other countries have the more potent pure S-ketamine enantiomeric form available which has twice the analgesic potency, and slightly less adverse cognitive effects in adults (Mion 2013 **NR**).

Perioperative use

Perioperative IV ketamine (IV bolus pooled with IV infusion) used in a large number of operations performed under general anaesthesia vs placebo reduces postoperative opioid consumption over 24 h by 19 % (MD 8 mg morphine equivalents; 95%CI 6 to 9) (65 RCTs, n=4,004) and over 48 h by 19 % (MD 13 mg; 95%CI 10 to 15) (37 RCTs, n=2,449) (Brinck 2018 **Level I** [Cochrane], 130 RCTs, n=8,341). Pain at rest is reduced by 19% at 24 h (MD -5/100; 95%CI -4 to -7) (82 RCTs; n=5,004) and at 48 h by 22 % (MD -5/100; 95%CI -3 to -7) (49 RCTs, n=2,962). Pain during movement is reduced in a similar way. Furthermore, PONV is reduced to a minor degree (23 % vs 27 %; RR 0.88; 95%CI 0.81 to 0.96) (NNT 24; 95%CI 16 to 54) (95 RCTs, n=5,965). The incidence of adverse events with ketamine (5%) vs placebo (4%) is similar (RR 1.2; 95%CI 0.95 to 1.4) (105 RCTs, n=6,538). A dose-dependent analgesic effect is not apparent.

Multiple further systematic reviews in subgroups have been performed with significant overlap of RCTs included.

Adding ketamine to an opioid in the PCA pump has similar benefits to the pooled data above on pain at rest at 24 h (WMD 21.1/100; 98%CI 21.8 to 20.39) (9 RCTs, n=595), opioid consumption (-28%) (7 RCTs, n=495) and PONV (-44%) (7 RCTs, n=435) (Assouline 2016 **Level I** [PRISMA], 19 RCTS, n=1,453). Respiratory depression (RR 0.31; 98%CI 0.06 to 1.51) (9 RCTs, n=871) and hallucinations (OR 1.16; 98%CI 0.47 to 2.79) (7 RCTs, n=690) are not increased. A parallel meta-analysis on ketamine added to morphine or hydromorphone PCA confirms these results (Wang 2016a **Level I** [PRISMA], 36 RCTs, n=2,502) (12 RCTs overlap).

Morphine/ketamine vs higher doses of morphine alone improves analgesia (MD 2.19/10; 95%CI 1.24 to 3.13) and wakefulness (MD -1.53/10; 95%CI -2.67 to -0.40) and reduces PONV (OR 3.71; 95%CI 2.37 to 5.80) and need for non-opioid rescue analgesia (Ding 2014 **Level I**, 7 RCTS, n=492).

Subanaesthetic doses of IM ketamine (escalating from 5 to 25 mg) injected two to three times 17 h to 4 h before cancer surgery reduced postoperative pain and morphine consumption in comparison to a single injection 4 h before surgery and placebo (Rakhman 2011 **Level II**, n=120, JS 5).

Results with regard to specific types of surgery:

- After thoracotomy, addition of ketamine to IV morphine PCA is opioid-sparing and improved analgesia in all RCTs and increases patient satisfaction in one (Mathews 2012 **Level I**, 5 RCTs, n=243). Improved respiratory outcomes (oxygen saturations and $PaCO_2$) are found in the RCTs assessing these parameters (2 RCTs, n=89). IV ketamine/fentanyl PCA resulted in comparable analgesia to thoracic epidural analgesia (Tseng 2019 **Level II**, n=70, JS 3);
- After knee arthroscopy, IV ketamine reduces pain intensity and opioid requirements as well as malonaldehyde levels as a measure of reperfusion injury (SMD -0.63; 95%CI -1.05 to -0.2) (2 RCTs, n=90), but not PONV (Pan 2019 **Level I** [PRISMA], 7 RCTs, n=300);
- After laparoscopic cholecystectomy, IV ketamine reduces pain intensity and opioid requirements at all time points up to 48 h, while reducing the incidence of PONV, pruritus and ileus (Zhu 2018a **Level I**, 6 RCTs, n=294; Ye 2017 **Level I**, 5 RCTs, n=212) (5 RCTs overlap);
- After Caesarean section under spinal anaesthesia (7 RCTs, n=562), but not under general anaesthesia (5 RCTs, n=391), parenteral ketamine improves pain intensity at 2 h, prolongs time to first analgesic request and reduces opioid requirements without increasing adverse effects except for diplopia in one RCT and nystagmus in 2 RCTs (Heesen 2015 **Level I** [PRISMA], 12 RCTs, n=953);
- After spinal surgery, ketamine reduces pain intensity and opioid requirements for 24 h without increased adverse effects (Pendi 2018 **Level I**, 14 RCTs, n=649). After spinal fusion surgery, perioperative IV ketamine bolus and infusion vs placebo resulted in improved long-term outcomes 1 y after surgery with reduced oral morphine (0 mg vs 20 mg) and other analgesic use, better pain relief at rest and on mobilisation (MD -17/100; 95%CI −30 to −3) and higher rate of return to work (43% vs 28%) (Nielsen 2019 **Level II**, n=147, JS 4);
- After laparoscopic gastric banding in obese patients, intraoperative ketamine infusion reduced pain and PCA opioid requirements (Andersen 2014b **Level I**, 1 RCT: Hasanein 2011, **Level II**, n=60, JS 3).

Subsequent to these meta-analyses, multiple further RCTs studying the same issue have been performed; overall the outcomes from these studies do not affect the existing conclusions and they are therefore not referenced here.

Low-dose parenteral ketamine may also improve analgesia in patients with opioid-induced tolerance or hyperalgesia. After spinal fusion in opioid-tolerant patients, use of a continuous ketamine infusion resulted in significantly less pain but did not reduce PCA opioid requirements in one RCT (Urban 2008 **Level II**, n=24, JS 4), however its use reduced opioid requirements and pain scores in the early postoperative period and at 6 wk in another (Loftus 2010 **Level II**, n=101, JS 4). Another trial in the same setting found reduced morphine requirements over 24 h (MD -42 mg; 95%CI -59 to -25), reduced sedation and improved function and disability at 6 mth (Nielsen 2017 **Level II**, n=150, JS 5). Similar results were found after noncancer surgery (Barreveld 2013b **Level II**, n=64, JS 5). A preoperative ketamine bolus for extracorporeal shock-wave lithotripsy reduced opioid requirements in chronic opioid users on low and high doses (Gharaei 2013 **Level II**, n=190, JS 4). However, when opioid-tolerant patients had epidural analgesia and IV PCA after spinal surgery, the addition of ketamine bolus and 24 h infusion conveyed no further benefit vs placebo (Subramaniam 2011 **Level II**, n=30, JS 5); the patients in this study also received gabapentin and antidepressants.

After remifentanil based anaesthesia, perioperative systemic ketamine reduces the development of acute tolerance/OIH associated with remifentanil use (Garcia-Henares 2018 **Level I** [PRISMA], 12 RCTs, n=569). This assessment is based on reduced postoperative pain scores and opioid requirements and increased time to first analgesic request and satisfaction scores in the ketamine vs the placebo groups but not on QST.

Use of a low-dose IV ketamine infusion 0.05 mg/kg/h for 24 h postoperatively reduced pain scores (over 48 h) in patients receiving epidural ropivacaine and morphine analgesia following thoracotomy (Suzuki 2006 **Level II**, n=49, JS 5). However, this was not confirmed by a subsequent study, where the addition of IV ketamine infusion 0.09 mg/kg/h for 48 h to epidural analgesia added no benefit (Joseph 2012 **Level II**, n=60, JS 5).

Perioperative ketamine vs placebo reduces the incidence of CPSP at 3 mth (5 RCTs, n unspecified) but only when administered for >24 h (OR 0.37; 95%CI 0.14 to 0.98) (Chaparro 2013 **Level I** [Cochrane] 14 RCTs [ketamine], n=1,388). At 6 mth (10 RCTs, n=516), perioperative ketamine reduces CPSP (OR 0.63; 95%CI 0.47 to 0.83), including when infused for <24 h (OR 0.45; 95 %CI 0.26 to 0.78). These effects were predominantly in abdominal surgery. Another meta-analysis found a benefit of perioperative IV ketamine vs placebo in reducing the incidence of CPSP at 3 mth (RR 0.74; 95%CI 0.60 to 0.93) (NNT 12), 6 mth (RR 0.70; 95%CI 0.50 to 0.98) (NNT 14) but not at 12 mth postoperatively (McNicol 2014 **Level I**, 14 RCTs [IV route], n=1,586) (11 RCTs overlap); such beneficial effects were not found with epidural administration of ketamine (3 RCTs, n=302). A subsequent meta-analysis found a benefit only at one mth, but is based on a much smaller number of included RCTs and speculates about the potential benefits of ketamine infusion >72 h and the role of epidural administration (Klatt 2015 **Level I** [PRISMA], 10 RCTs, n=784) (6 RCTs overlap with Chaparro 2013, all 10 RCTs overlap with McNicol 2014).

Ketamine has an effect on the regulation of inflammation by inhibiting inflammatory cell recruitment, cytokine production and downregulating inflammatory mediators (Loix 2011 **NR**). Intraoperative administration of ketamine has an inhibitory effect on the early postoperative IL-6 inflammatory response (MD -71 pg/mL; 95%CI -101 to -41) (Dale 2012 **Level I** [PRISMA], 6 RCTs, n=331).

Other acute pain indications

IV ketamine pretreatment reduces pain from propofol injection vs no pretreatment (OR 0.52; 95%CI 0.46 to 0.57) (Jalota 2011 **Level I**, 7 RCTs, n=910).

Ketamine has also some analgesic efficacy in burns patients (McGuinness 2011 **Level I**, 4 RCTs, n=67) (see also Section 8.5).

In the ICU, ketamine acts as a potent analgesic, sedative agent and bronchodilator with positive effects on haemodynamics (Patanwala 2017 **Level IV SR** [PRISMA], 6 RCTs, n=223 & 6 studies).

See also Section 8.10.5.5.

Low dose ketamine 0.1 to 0.3 mg/kg IV is considered a safe and efficacious analgesic in the ED either as single therapy or in combination with IV morphine 0.1 mg/kg (Karlow 2018 **Level I** [PRISMA], 3 RCTs, n=261; Ghate 2018 **Level IV SR** [PRISMA], 6 RCTs, n=544 & 2 studies, n=65) (2 RCTs overlap). See also Section 8.11.1.4.

Ketamine is also a safe and effective analgesic for pain due to trauma in the prehospital setting (Jennings 2011 **Level IV SR**, 2 RCTs & 4 studies, n=340). See also Section 8.12.2.4.

Guidelines for the use of ketamine infusions in acute pain support its use in painful surgery, for opioid-dependent or opioid-tolerant patients undergoing surgery or with acute or chronic sickle cell pain and possibly for patients with sleep apnoea to limit opioid use (Schwenk 2018 **GL**).

Adverse effects with short-term systemic administration of ketamine

Overall, CNS adverse events (eg hallucinations and nightmares) were increased vs placebo in 52 studies, while 53 studies reported no increase (Brinck 2018 **Level I** [Cochrane], 130 RCTs, n=8,341). Pooled incidence of CNS adverse effects is not increased (RR 1.2; 95%CI 0.95 to 1.4) (105 RCTs, n=6,538). The incidence of hallucinations is reported as not increased when ketamine is combined with the opioid in a PCA pump (OR 1.16; 98%CI 0.47 to 2.79) (7 RCTs, n=690) (Assouline 2016 **Level I** [PRISMA], 19 RCTS, n=1,453).

The incidence can be reduced with a gradual dose increase (Okamoto 2013 **Level IV**, n=46). For IV administration, slow IV infusion of 0.3 mg/kg ketamine resulted in lower rates of CNS adverse effects than IV bolus injection (Clattenburg 2018 **Level II**, n=62, JS 5; Motov 2017 **Level II**, n=48, JS 5).

Contrary to common beliefs, IV ketamine does not increase intracranial pressure or reduce cranial perfusion pressure vs opioids (Wang 2014 **Level I**, 5 RCTs, n=198). This is also true for patients with nontraumatic neurological diseases (Zeiler 2014 **Level IV SR**, 16 studies, n=127 [adult] & n=87 [children]).

Chronic pain

Ketamine has efficacy in treatment of chronic neuropathic pain (15 of 23 RCTs positive [ketamine]) (Aiyer 2018 **Level I** [PRISMA], 58 RCTs, n unspecified).

IV ketamine is superior to placebo and comparable to IV lidocaine and IV alfentanil in the treatment of pain after SCI (Teasell 2010 **Level I**, 2 RCTs [ketamine], n=19). See also Section 8.2.1.

IV ketamine reduces phantom limb pain short-term with some possible long-term benefit (Alviar 2016 **Level I** [Cochrane], 2 RCTs [ketamine], n=31; McCormick 2014 **Level I**, 4 RCTs, n=107) (2 RCTs overlap). See also Section 8.1.5.2.

Ketamine by various routes of administration (IV, oral, topical) is also a successful treatment for Complex Regional Pain Syndrome (CRPS) based on limited evidence (Zhao 2018 **Level III-2 SR**, 1 RCT & 14 studies, n=258; Azari 2012 **Level IV SR**, 3 RCTS & 16 studies, n unspecified).

In view of the risks described below, current use of ketamine to treat chronic pain should be restricted to therapy-resistant severe neuropathic pain (Niesters 2014a **NR**; Tawfic 2013 **NR**); recent evidence-based guidelines outline a cautious approach with possibly best indications in spinal cord injury pain and CRPS (Cohen 2018 **GL**). A draft of a practice guideline has been published by FPMANZCA (FPMANZCA 2020 **GL**).

Cancer pain

Ketamine is a viable therapeutic option in treating refractory cancer pain despite limitations in the data available (Bredlau 2013 **Level IV SR**, 5 RCTs and 6 studies, n=483); however, the largest RCT included showed no clinical benefit when ketamine was added to opioids for cancer-pain treatment (Hardy 2012 **Level II**, n=187, JS 5). A subsequent Cochrane review of ketamine as an adjunct to opioids in cancer pain excluded most of the RCTs considered above and regards the current evidence as insufficient to assess the benefits and harms of ketamine as an adjuvant to

opioids for the relief of refractory cancer pain (Bell 2017 **Level I** [Cochrane] 3 RCTs, n=217). See also Section 8.9.3.3.

Adverse effects with long-term systemic administration of ketamine

Ketamine has an abuse potential (Morgan 2012 **NR**) with highest abuse rates in South-East Asia and China (Liu 2016 **NR**; Kalsi 2011 **NR**). Heavy use of ketamine has consequences on cognitive and emotional function (Morgan 2010 **NR**) and there are increasing consequences including traffic accidents when under its influence (Liu 2016 **NR**). Acute toxicity leads to confusion, drowsiness, or transient loss of consciousness, while symptoms of chronic toxicity are "ketamine cystitis" and chronic abdominal pain (Yiu-Cheung 2012 **NR**) as well as hepatotoxicity. The latter issues need to be considered when using ketamine in a chronic setting therapeutically (Bell 2012 **NR**) and may limit its indications (Cohen 2018 **GL**; Niesters 2014a **NR**).

Other routes of systemic administration and bioavailability

Ketamine is most commonly administered as a continuous low-dose IV infusion, however SC infusion is also used, especially in palliative care, with a bioavailability (similar to IM) of approximately 90% (Clements 1982 **PK**). Sublingual (SL), IN and TD routes have also been used for acute pain management (Peltoniemi 2016 **NR PK**) (see Chapter 5).

A pharmacokinetic study in healthy volunteers calculated the bioavailability of oral ketamine as 20%, SL 30% and IN 45%; the pharmacodynamic effects of the active metabolite norketamine were thought to be of potential significance (Yanagihara 2003 **PK**). The bioavailability of a 25 mg ketamine lozenge was 24% when given by both SL and oral routes; peak plasma levels were seen at 30 min and 120 min respectively and terminal half-lives were similar at around 5 h (Chong 2009 **PK**). For both routes, norketamine concentrations exceeded the concentrations of ketamine and, given its pharmacological activity profile, norketamine is therefore likely to be a major contributor to the overall analgesic effect. A SL ketamine wafer achieved rapid absorption with a bioavailability of 29% (Rolan 2014 **PK**).

4.6.1.2 | Dextromethorphan

In a meta-analysis of experimental studies (oral administration 11 RCTs; IV administration 1 RCT) (mean dose 0.92 mg/kg [range 0.17 to 2.71 mg/kg]), dextromethorphan has no effect on area of hyperalgesia (4 RCTs) nor on pain intensity (SMD 0.07; 95%CI -0.21 to 0.34) (10 RCTs, n=132) (Thompson 2019 **Level I EH** [(PRISMA]), 70 RCTs, n=1,069). However, PO dextromethorphan 30 mg in a model of primary and secondary hyperalgesia (freeze-injury pain model) had antihyperalgesic effects on both phenomena, while it has no anti-nociceptive effect in areas of healthy skin (Martin 2019a **Level II EH**, n=20, JS 5).

In postoperative pain, dextromethorphan reduces pain at 1 h (MD -1.60/10; 95%CI -1.89 to -1.31) (13 RCTs, n=884), 4 to 6 h and 24 h as well as opioid requirements (IV MED MD -10.51 mg; 95%CI -16.48 to -4.53) (14 RCTs, n=848) (King 2016 **Level I**, 21 RCTs, n=1,520).

As dextromethorphan is metabolised by CYP2D6 to the inactive metabolite dextrorphan, the effect of the CYP2D6 inhibitor quinidine before PO dextromethorphan 50 mg administration has been assessed in knee ligament surgery (Ehret 2013 **Level II**, n=48, JS 4). Dextromethorphan concentrations were higher after quinidine than after placebo and resulted in lower rescue analgesia requirements. PO dextromethorphan/quinidine provided superior pain relief vs placebo in diabetic polyneuropathy (Shaibani 2012 **Level II**, n=379, JS 3).

PO dextromethorphan 120 to 180 mg reduces chronic phantom limb pain vs placebo (Alviar 2016 **Level I** [Cochrane], 1 RCT [dextromethorphan]: Ben Abraham 2003 **Level II**, n=10 [triple phase cross over], JS 3).

Dextromethorphan may have efficacy in chronic neuropathic pain (4 of 6 RCTs), possibly with less benefit in PHN (Aiyer 2018 **Level I** [PRISMA], 58 RCTs, n unspecified). After IV ketamine treatment of neuropathic pain, PO dextromethorphan extended treatment effects for one mth vs placebo (Martin 2019b **Level II**, n=60, JS 4).

PO dextromethorphan therapy (titrated to 480 mg/d) for 5 wk was not effective in reversing methadone-induced hyperalgesia (Compton 2008 **Level III-1**).

4.6.1.3 | Magnesium

Magnesium is regarded as an NMDA-receptor antagonist as its primary mechanism of action; however, magnesium also blocks calcium channels and modulates potassium channels and may have an antinociceptive effect through the activation of the nitric oxide (NO) pathway (Srebro 2016 **NR**). It has also anti-inflammatory effects by reducing IL-6 and TNF-alpha plasma levels in the postoperative setting, which might contribute to the effects described here (Aryana 2014 **Level II**, n=90, JS 4).

Magnesium IV as an adjunct to morphine IV analgesia has an opioid-sparing effect (MED WMD -7.4 mg; 95%CI -9.4 to -5.4) without reducing PONV but with improved pain scores at 4 to 6 h (Murphy 2013 **Level I**, 22 RCTs, n=1,177). This is in line with two parallel meta-analyses: one also describes an opioid-sparing effect (MED WMD -10.52 mg; 99%CI -13.50 to -7.54) and reduction of pain at rest (4 and 24 h) and on movement (24 h) (De Oliveira 2013c **Level I** [PRISMA], 20 RCTs, n=1,257) (most RCTs overlap); the second draws similar conclusions and found no significant adverse effects (Albrecht 2013 **Level I**, 25 RCTs, n=1,461) (most RCTs overlap).

Subsequent to these three meta-analyses, multiple further meta-analyses and RCTs exploring the same issues after different types of surgery or anaesthesia with significant overlap of included RCTs conclude:

- After orthopaedic surgery, IV magnesium reduces postoperative analgesic consumption, PONV and shivering (Peng 2018 **Level I** [PRISMA], 11 RCTs, n=535). Pain intensity is reduced in 6 of 11 RCTs;
- After laparoscopic cholecystectomy, IV magnesium reduces pain intensity at 2 and 8 h and analgesic consumption (Chen 2018a **Level I**, 4 RCTs, n=463);
- After Caesarean section, a qualitative systematic review showed that IV magnesium may reduce postoperative pain intensity (McKeown 2017 **Level I**, 7 RCTs, n=530);
- In paediatric tonsillectomy, magnesium administered by local infiltration or IV (bolus ± infusion) has analgesic effects (Xie 2017 **Level I** [PRISMA], 10 RCTs n=665; Cho 2018 **Level I** [PRISMA], 10 RCTs, n=615) (9 RCTs overlap). See also Section 10.4.7.2;
- After spinal anaesthesia, IV magnesium prolonged the duration of sensory block for abdominal hysterectomy and reduced postoperative pain scores in the first 4 h after surgery (Kahraman 2014 **Level II**, n=40, JS 5). After spinal anaesthesia for umbilical hernia repair, IV magnesium prolonged time to first rescue analgesia and was opioid-sparing in the first 24 h after surgery (Kumar 2013 **Level II**, n=60, JS 5). This was also found after spinal anaesthesia for THA, where IV magnesium reduced postoperative pain scores and opioid requirements for 48 h, while increasing serum magnesium concentrations (Hwang 2010 **Level II**, n=40, JS 5). However, IV magnesium did not change magnesium concentrations in the CSF (Mercieri 2012 **Level II**, n=45, JS 3).

Subsequent to these meta-analyses, multiple further RCTs studying the same issue have been performed; overall the outcomes from these studies do not affect the existing conclusions and they are therefore not referenced here.

Magnesium reduces the development of acute tolerance/OIH associated with remifentanil use (Wu 2015 **Level I** [QUOROM], 5 RCTs [magnesium], n=729).

Combining ketamine with IV magnesium reduced 48 h morphine consumption by 30% vs ketamine alone after scoliosis surgery (Jabbour 2014 **Level II**, n=50, JS 5). While pain scores were not different, sleep quality and patient satisfaction were improved with the combination treatment.

IV magnesium may also have other beneficial effects on postoperative recovery; after segmental mastectomy in an outpatient setting, patients receiving IV magnesium had better quality of recovery (QoR) scores at 24 h vs saline (MD 24/40; 99%CI 3 to 33) and reduced opioid requirements after discharge (De Oliveira 2013a **Level II**, n=50, JS 5). There were significant linear relationships between the postoperative systemic magnesium concentrations and 24 h postoperative QoR scores as well as with pain burden (inverse).

IV magnesium sulphate 4 g attenuated tourniquet pain in healthy volunteers (Satsumae 2013 **Level II EH**, n=24, JS 5).

IV magnesium in treatment of acute migraine attacks vs placebo or active comparators is superior at time points 15-45 min (OR 0.23; 95%CI 0.09 to 0.58) (6 RCTs), 2 h (OR 0.20; 95%CI 0.10 to 0.40) [5 RCTs] and 24 h (OR 0.25; 95%CI 0.10 to 0.60) [4 RCTs] (Chiu 2016 **Level I** [PRISMA], 11 RCTs, n=948).

IV magnesium was non-inferior to IV dexamethasone for the prevention of postoperative sore throat after lumbar spinal surgery in the prone position (Park 2015 **Level II**, n=146, JS 5).

IV magnesium has only at best anecdotal evidence for an effect on any outcome of Irukandji syndrome, caused by jellyfish sting in Northern Queensland (Rathbone 2017 **Level IV SR** 1 RCT & 8 studies, [n=291 Mg recipients]); the only RCT included showed no beneficial effect (McCullagh 2012 **Level II**, n=39, JS 5).

Oral magnesium daily for 4 wk had no beneficial effect in the treatment of neuropathic pain (Pickering 2011 **Level II**, n=45, JS 5). IV or oral magnesium therapy has been shown to have no effect on reducing painful crisis and hospital LOS in treating sickle cell disease (Than 2019 **Level I** [Cochrane], 5 RCTs, n=386). Oral magnesium (65 mg elemental/d) was also not improving analgesia when added in cancer pain patients treated with oral morphine (Baaklini 2017 **Level II**, n=43, JS 5). IV magnesium vs IV lidocaine provided inferior analgesia for propofol injection pain; IV magnesium/IV lidocaine offered no advantage over IV lidocaine alone (Galgon 2015 **Level II**, n=200, JS 5).

See Section 5.7.1.4 for magnesium use via the IT route and Section 10.4.7.2 for paediatric use.

4.6.1.4 | Amantadine and memantine

A bolus dose of IV amantadine had no effect on postoperative analgesia after abdominal hysterectomy (Gottschalk 2001 **Level II**, n=30, JS 4). However, after radical prostatectomy, perioperative oral amantadine reduced morphine consumption, wound pain on palpation and bladder spasms (Snijdelaar 2004 **Level II**, n=24, JS 4). After spinal surgery, premedication with oral amantadine reduced not only intraoperative fentanyl requirements but also postoperative pain intensity and opioid requirements in the first 48 h by 25% (Bujak-Gizycka 2012 **Level II**, n=60, JS 5).

Oral memantine shows analgesic effects in acute [4 studies, n=24], but not in chronic phantom limb pain [4 RCTs, n=104] (Loy 2016 **Level IV SR**, 5 RCTs, 2 case series & 1 case report, n=128).

Memantine administered perioperatively was not effective in reducing the incidence of postmastectomy pain syndrome (Eisenberg 2007 **Level II**, n=22, JS 5); however, a subsequent trial showed a reduction in postmastectomy pain, analgesic consumption and better emotional state at 3 mths (Morel 2016 **Level II**, n=43, JS 5).

Memantine may have some benefits in neuropathic pain (Pickering 2018 **NR**).

KEY MESSAGES

1. Perioperative IV ketamine reduces opioid consumption, pain intensity and postoperative nausea and vomiting compared to placebo (**S**) (**Level I** [Cochrane Review]); similar outcomes are achieved when ketamine is added to an opioid in a PCA pump (**S**) (**Level I** [PRISMA]).
2. Perioperative IV ketamine reduces the incidence of chronic postsurgical pain in selected procedures (**S**) (**Level I** [Cochrane Review]).
3. NMDA-receptor antagonists reduce the development of acute tolerance/opioid-induced hyperalgesia associated with remifentanil use (**S**) (**Level I** [PRISMA]).
4. IV ketamine reduces ischaemic pain intensity in critical limb ischaemia (**N**) (**Level I** [PRISMA]).
5. IV magnesium as an adjunct to morphine analgesia has an opioid-sparing effect and improves pain scores (**S**) (**Level I** [PRISMA]).
6. IV magnesium is effective in treatment of acute migraine attacks (**N**) (**Level I** [PRISMA]).
7. IV ketamine is effective in the treatment of neuropathic pain following spinal cord injury (**U**) (**Level I**).
8. Morphine/ketamine compared with higher doses of morphine alone improves analgesia and reduces sedation and postoperative nausea and vomiting in postoperative patients (**U**) (**Level I**).
9. IV ketamine does not increase intracranial pressure or reduce cranial perfusion pressure compared to opioids (**U**) (**Level I**).
10. Perioperative dextromethorphan reduces opioid consumption and pain intensity compared to placebo (**N**) (**Level I**)
11. Ketamine is a safe and effective analgesic in the prehospital setting (**U**) (**Level II**).
12. Ketamine reduces postoperative pain and opioid requirements in opioid-tolerant patients (**S**) (**Level II**).
13. IV magnesium extends the duration of sensory block with spinal anaesthesia and reduces subsequent postoperative pain (**N**) (**Level II**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Increasing rates of ketamine abuse are reported, in particular from South-East Asia and China (**S**).

☑ Ketamine toxicity leads to cognitive impairment and abuse to chronic organ toxicity (bladder, liver) (**U**).

4.6.2 | Regional NMDA-receptor antagonists

4.6.2.1 | Ketamine

Neuraxial

Some commercially available preparations of ketamine have a low pH (3.5 to 5.5) and contain an untested preservative (benzethonium chloride) and thus cannot be recommended for IT use in humans (de Lima 2000 **NR**; Hodgson 1999 **NR**). Subarachnoid administration of S(+)-ketamine without preservative caused histological lesions on the spinal cord and meninges in dogs (Gomes 2011 **BS**). Concerns of local neurotoxicity *in vitro* continue to limit the use of neuraxial ketamine, in particular when combined with lidocaine (Werdehausen 2011 **NR**).

The addition of IT racemic ketamine to bupivacaine did not prolong postoperative analgesia or reduce analgesic requirements but led to significantly more nausea and vomiting, sedation, dizziness, nystagmus and "strange feelings" (Kathirvel 2000 **Level II**, n=30, JS 2). IT S(+)-ketamine with bupivacaine for Caesarean section decreased time to onset and increased spread of the block but did not prolong duration vs fentanyl (Unlugenc 2006 **Level II**, n=90, JS 5). However, IT ketamine/morphine/bupivacine was superior to IT morphine/bupivacaine or IT ketamine/bupivacaine for major abdominal cancer surgery with regard to pain intensity, opioid requirements and time to rescue analgesia (Abd El-Rahman 2018b **Level II**, n=90, JS 3).

The combination of epidural ketamine with epidural opioid-based (±local anaesthetic) solutions improves pain relief and may reduce overall opioid requirements without increasing the incidence of adverse effects (Subramaniam 2004 **Level I,** 8 RCTs [epidural], n=513; Walker 2002 **Level I**, 4 RCTs [epidural], n=211). Ketamine IV may be as effective as epidural ketamine in reducing hyperalgesia. Epidural racemic ketamine improved early postoperative analgesia when used with bupivacaine for lower limb amputations, although pain at 1 y was not different; perioperative opioids were not used (Wilson 2008 **Level II**, n=47, JS 5).

Ketamine 0.25 to 0.5 mg/kg added to caudal local anaesthetic prolongs time to first analgesic request by a median difference of 5.6 h without prolonged motor block (Schnabel 2011 **Level I** [PRISMA], 13 RCTs, n=884); 0.5 mg/kg increases block duration and reduces postoperative analgesic requirements (Dahmani 2011 **Level I** [QUORUM], 10 RCTs [caudal], n=686) (6 RCT overlap). Although some adverse effects are more frequent in the ketamine group (eg sedation), there was no significant difference to placebo. Caudal ketamine prolonged analgesia when administered with caudal bupivacaine but was less effective than midazolam or neostigmine as caudal adjuvants (Kumar 2005 **Level II**, n=80, JS 5). See also Section 10.4.7.1 and 10.6.3.3.

Peripheral sites

Use of ketamine alone or with local anaesthesia for PNB or local infiltration shows contradictory results, possibly due to systemic effects. Systemic comparators are not included in most RCTs.

No analgesic benefit for PNB was shown in brachial plexus block for arm surgery (Lee 2002 **Level II**, n=51, JS 4), IA injection (where IV ketamine provided better analgesia) (Rosseland 2003 **Level II**, n=77, JS 5) or wound infiltration such as following Caesarean section (Zohar 2002 **Level II**, n=50, JS 5) or inguinal hernia repair (Clerc 2005 **Level II**, n=36, JS 2). Adding ketamine to lidocaine IVRA did not result in better pain relief vs IV ketamine (Viscomi 2009 **Level II**, n=36, JS 4). When added to lidocaine for axillary brachial plexus block, ketamine 50 mg only modestly increased duration of sensory and motor block vs placebo (114.8 ± 12.5 min v. 106.2 ± 7.9 min), much less than dexamethasone (174.4 ± 13.1 min) (Zaman 2017 **Level II**, n=78, JS 5). Significant nystagmus, increased heart rate and blood pressure were observed in the ketamine group.

However, in pectoral block for mastectomy, ketamine 1 mg/kg added to bupivacaine 0.25% 30 mL vs bupivacaine alone prolonged time to first analgesic request and reduced opioid

requirements (Othman 2016 **Level II**, n=60, JS 3). IA ketamine 1 mg/kg provided analgesia superior to placebo, but inferior to IA ketamine 0.5 mg/kg in levobupivacaine 0.25% 20 mL after arthroscopic meniscectomy (Isik 2015 **Level II**, n=6, JS 3). In circumcision, pain scores were lower with preincisional ketamine vs saline (Tan 2007 **Level II**, n=40, JS 4). Adding ketamine 2 mg/kg to bupivacaine 0.25% 40 mL resulted in comparable analgesia to adding dexmedetomidine 2 mcg/kg to local wound infiltration after abdominal hysterectomy; both mixtures were superior to bupivacaine alone (Mohamed 2018 **Level II**, n=90, JS 5). Following thyroidectomy, wound infiltration with ketamine 1 mg/kg provided superior analgesia to IM ketamine 1 mg/kg and both groups were superior to placebo (Abd El-Rahman 2018a **Level II**, n=90, JS 5). After rhinoplasty, the addition of ketamine 0.5 mg/kg to lidocaine for submucosal infiltration provided superior analgesia to lidocaine alone with both being superior to placebo (Sanli 2016 **Level II**, n=90, JS 4).

Topical administration

Ketamine gargle vs placebo or no treatment reduces the incidence of postoperative sore throat up to 24 h postoperatively (RR 0.42 to 0.52 over time points 0 to 24 h) based on high-quality evidence (Mayhood 2015 **Level I** [PRISMA], 5 RCTs, n=291); systemic absorption is an unknown factor.

After mandibular molar extraction, topical administration (to the extraction sockets on resorbable gelatin sponges) of ketamine 0.5 mg/kg vs tramadol 1 mg/kg and vs saline achieved the lowest pain scores and rescue analgesic use for the first 24 h after surgery (Gonul 2015 **Level II**, n=90, JS 2). In a similar setting, the addition of ketamine 0.3 mg/kg to lidocaine 2% for the local anaesthesia (Inferior alveolar, lingual and buccal nerve blocks) reduced pain at 1 and 4 h and facial swelling at 1 d, while improving mouth opening up to 7 d (Kumar 2015 **Level II**, n=60, JS 1).

Topical ketamine-amitriptyline did not reduce chemotherapy-induced peripheral neuropathic pain (Gewandter 2014 **Level II**, n=462, JS 5).

4.6.2.2 | Magnesium

Magnesium influences neuronal calcium influx and may exert an analgesic effect on NMDA receptors in the spinal cord (Bailard 2014 **NR**). The long-term effects of perineural or neuraxial magnesium have not been clarified.

Neuraxial magnesium for Caesarean section prolongs duration of sensory and motor block, time to first rescue analgesic requirement and reduces pain intensity and analgesic requirements without an effect on PONV, pruritus, hypotension, shivering or sedation (Wang 2017a **Level I** [PRISMA], 9 RCTs, n=827).

IT magnesium combined with lipophilic opioid, with or without local anaesthetic, prolongs the duration of spinal analgesia in nonobstetric populations also (SMD 1.38; 95%CI 0.6 to 2.11) (Morrison 2013 **Level I**, 15 RCTs, n=980). There is no increase in adverse effects. There was a high degree of heterogeneity, including magnesium dose, making any firm conclusion difficult. This was supported by a parallel meta-analysis (Pascual-Ramirez 2013 **Level I**, 12 RCTs, n=817) (9 RCTs overlap).

Epidural magnesium 50 mg added to bupivacaine 12.5 mg/morphine 2 mg improved analgesia after thoracotomy for the first 4 h and reduced rescue analgesia requirements vs placebo/ bupivacaine 12.5 mg/morphine 2 mg (Farzanegan 2018 **Level III-1**, n=80).

Magnesium added to perineural block prolongs analgesia (MD 125 min; 95%CI 65 to 184), sensory and motor block (Li 2016b **Level I** [PRISMA], 7 RCTs, n=493). Subsequent RCTs have confirmed these findings in femoral nerve block in the prehospital setting (Jebali 2018 **Level II**, n=48, JS 4), TAPB after abdominal hysterectomy (Abd-Elsalam 2017 **Level II**, n=60, JS 4) and sciatic nerve block for toe amputation (Sun 2017a **Level II**, n=70, JS 5). The mechanism of action of magnesium at perineural sites is uncertain and safety and outcome data are limited suggesting caution should be exercised (Bailard 2014 **NR**).

Oral topical magnesium reduces postoperative sore throat incidence (RR 0.22; 95%CI 0.12 to 0.39 [at 24 h postoperatively]) and severity after orotracheal intubation (Singh 2019 **Level I** [PRISMA] 7 RCTs, n=726).

IA magnesium versus placebo after arthroscopic surgery improves pain control [5 RCTs] and prolongs time to first analgesic request [4 RCTs] (Zeng 2016 **Level I** [PRISMA], 8 RCTs, n=513). The combination magnesium/bupivacaine versus bupivacaine only prolongs time to first analgesic request only [4 RCTs]. Magnesium vs bupivacaine results in similar analgesia [3 RCTs]. No relevant adverse effects were described in any study. Magnesium/levobupivacaine vs levobupivacaine alone and vs placebo after arthroscopic meniscectomy reduced pain intensity and rescue analgesic requirements (Kizilcik 2017 **Level II**, n=96, JS 4).

Magnesium added to lidocaine IVRA improved intra and postoperative analgesia and tourniquet tolerance (Kashefi 2008 **Level II**, n=40, JS 4; Turan 2005 **Level II**, n=30, JS 4).

KEY MESSAGES

1. Neuraxial magnesium reduces pain intensity and analgesic requirements after Caesarean section (**N**) (**Level I** [PRISMA].
2. Oral topical magnesium or ketamine (as gargle or lozenge) reduce the incidence of postoperative sore throat (**N**) (**Level I** [PRISMA].
3. Intra-articular magnesium improves analgesia after arthroscopic surgery compared to placebo (**N**) (**Level I** [PRISMA].
4. Magnesium added to local anaesthetics in peripheral nerve blocks prolongs sensory block and analgesic effects (**N**) (**Level I** [PRISMA].
5. Epidural ketamine (without preservative) added to opioid-based epidural analgesia regimens improves pain relief without reducing adverse effects (**U**) (**Level I**).
6. Caudal ketamine in children, in combination with local anaesthetic or as the sole medication, improved and prolonged analgesia with few adverse effects (**U**) (**Level I**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Variable results for regional and topical administration of ketamine and magnesium may reflect systemic effects (**N**).

4.7 | Antidepressant medicines

4.7.1 | Acute pain

There are limited published data on the use of antidepressants in the management of acute nociceptive and neuropathic pain.

4.7.1.1 | Tricyclic antidepressants

Amitriptyline given to patients with acute herpes zoster reduced the incidence of postherpetic neuralgia at 6 mth (Bowsher 1997 **Level II**, n=80, JS 5). Amitriptyline given after orthopaedic surgery did not improve opioid analgesia vs placebo (Kerrick 1993 **Level II**, n=28, JS 5).

Desipramine, but not amitriptyline, given prior to dental surgery increased and prolonged the analgesic effect of a single dose of morphine, but both had no analgesic effect on their own (Levine 1986 **Level II**, n=30, JS 3). When used for a fortnight in experimental pain, desipramine had no effect on pain or hyperalgesia (Wallace 2002 **Level II EH**, n=13, JS 4).

4.7.1.2 | Serotonin–norepinephrine-reuptake inhibitors

After TKA, duloxetine 60 mg (preoperative and on POD 1) had an opioid-sparing effect (35%) vs placebo (Ho 2010 **Level II**, n=50, JS 5). In patients with an increased Central Sensitisation Inventory (CSI), duloxetine 30 mg (before surgery and daily for 6 wk thereafter) improved pain control, physical and emotional functioning and patient satisfaction with analgesia for 2 to 12 wk after TKA vs control (Koh 2019 **Level II**, n=40, JS 5). However, duloxetine 60 mg (for 2 wk) had no effect on subacute pain with ambulation after TKA vs placebo, when used as a component of a multimodal analgesia regimen (YaDeau 2016 **Level II**, n=106, JS 5). Venlafaxine 37.5 mg was as effective as gabapentin 300 mg in reducing pain at rest and analgesic requirements, when given perioperatively for 10 d in mastectomy vs placebo (Amr 2010 **Level II**, n=150, JS 4). Venlafaxine was inferior to gabapentin in reducing pain on movement; however, at 6 mth postoperatively, fewer patients in the venlafaxine group reported chronic pain or analgesic use.

4.7.1.3 | Selective serotonin-reuptake inhibitors

In patients with high preoperative pain catastrophising scale (PCS) scores, escitalopram 10 mg (preoperatively and for 6 d postoperatively) did not reduce pain on mobilisation at 24 h after total knee replacement vs placebo (Lunn 2015 **Level II**, n=120, JS 5). On POD 2 to 6, pain at rest and mobilisation was lower in the treatment group.

4.7.2 | Chronic pain

Treatment guidelines for chronic neuropathic pain recommend TCAs and SNRIs, but not SSRIs, as first-line treatment in this indication (Finnerup 2015 **GL Level I** [PRISMA], 229 RCTs, n unspecified).

4.7.2.1 | Tricyclic antidepressants

While TCAs are seen as the first-line therapy in neuropathic pain treatment, data are of disappointing quality. None of the supportive studies are of high quality and low risk of bias (Moore 2015a **Level I** [Cochrane], 17 RCTs, n=1,342). Adverse events are increased with amitriptyline (RR 1.5; 95%CI 1.3 to 1.8) (NNH 5.2; 95%CI 3.6 to 9.1). Similarly, imipramine (Hearn 2014 **Level I**

[Cochrane], 5 RCTs, n=168) and nortriptyline are supported only by very low-quality evidence in this indication (Derry 2015b **Level I** [Cochrane], 6 RCTs, n=310). For fibromyalgia, the evidence is also low quality for amitriptyline (NNT 4.1 for ≥50% pain relief and NNH 3.3) (Moore 2015a **Level I** [Cochrane] 9 RCTs, n=649).

In elderly patients, TCAs should possibly be avoided as the use of medications with anticholinergic activity increases risk of cognitive impairment and even mortality in this patient group (Fox 2011 **Level III-2**, n=13,004).

4.7.2.2 | Serotonin–norepinephrine-reuptake inhibitors

Duloxetine 60 to 120 mg/d provides analgesia for diabetic neuropathy (Lunn 2014 **Level I** [Cochrane], 8 RCTs, n=2,728; Hossain 2016 **Level I** [PRISMA], 8 RCTs, n=4,084) (7 RCTs overlap). RCTs supporting the use of venlafaxine in neuropathic pain have a high risk of bias (Gallagher 2015 **Level I** [Cochrane], 6 RCTs, n=460; Aiyer 2017 **Level I** [PRISMA], 13 RCTs, n=851) (6 RCTs overlap). There is no evidence for an effect of milnacipran in neuropathic pain (Derry 2015b **Level I** [Cochrane], 1 unpublished RCT: [NCT01225068], n=40).

SNRIs also have limited analgesic effects in fibromyalgia (NNT 5-11 vs placebo depending on outcome assessed) (Welsch 2018 **Level I** [Cochrane], 18 RCTs, n=7,903). This has been confirmed specifically for milnacipran (Cording 2015 **Level I** [Cochrane], 6 RCTs, n=4,238). Duloxetine and milnacipran have comparable efficacy in this indication (Lee 2016 **Level I** [NMA], 9 RCTs, n=5,140) (4 RCTs overlap).

4.7.2.3 | Selective serotonin-reuptake inhibitors

There is only limited evidence for the effectiveness of SSRIs in neuropathic pain (Saarto 2007 **Level I** [Cochrane] 61 RCTs, n=3,293). Similarly, there is only biased evidence that SSRIs are superior to placebo in treating the key symptoms of fibromyalgia: namely pain, fatigue and sleep problems (Walitt 2015 **Level I** [Cochrane], 7 RCTs, n=383).

4.7.3 | Specific pain conditions

In postherpetic neuralgia, TCAs are less effective than pregabalin and 5% lidocaine medicated plaster (Snedecor 2014 **Level I**, 28 RCTs, n=4,317). In diabetic polyneuropathy, amitriptyline is the least effective of the medications studied with the worst benefit-risk balance, while venlafaxine and duloxetine were the superior antidepressants here (Rudroju 2013 **Level I**, 21 RCTs, n=4,219).

In fibromyalgia, amitriptyline (NNT 4.9) and the serotonin–norepinephrine-reuptake inhibitors (SNRIs) duloxetine and milnacipran (NNT 10) were the most effective antidepressants (Hauser 2012 **Level I**, 35 RCTs, n=6,766).

In chronic headaches, antidepressants are effective in treatment and prophylaxis with better efficacy of TCAs than SSRIs (Jackson 2017 **Level I** [PRISMA], 21 RCTs, n=2,751; Jackson 2010 **Level I** [PRISMA], 37 RCTs, n=3,176). Use of SSRIs and SNRIs for migraine prophylaxis (Banzi 2015 **Level I** [Cochrane], 12 RCTs, n=585) and prevention of chronic tension type headache is not supported by evidence (Banzi 2015 **Level I** [Cochrane], 8 RCTs, n=412).

In chronic low-back pain, antidepressants neither improve pain nor depression (Urquhart 2008 **Level I** [Cochrane], 10 RCTs, n=706); this was confirmed in a subsequent systematic review of pharmacological interventions in this indication (Kuijpers 2011 **Level I**, 5 RCTs, n=303). However, these results are challenged as they did not differentiate between different antidepressants; SNRIs like duloxetine (Williamson 2014 **Level I**, 3 RCTs, n=982) and TCAs may be effective, while SSRIs are not (Staiger 2003 **Level I**, 7 RCTs, n=440).

There is only poor evidence for an analgesic effect of any antidepressant in orofacial pain disorders (Martin 2012 **Level I**, 6 RCTs, n=208) and for an analgesic effect of TCAs or SSRIs in rheumatoid arthritis (Richards 2011 **Level I** [Cochrane], 8 RCTs, n=652).

Duloxetine improves WOMAC scores in osteoarthritis to an extent comparable to other first-line treatments for osteoarthritis (eg NSAIDs) (Myers 2014 **Level I**, 3 RCTs, n=775). Duloxetine results in a greater reduction in pain, improved function and patient rated impression of improvement for treatment of osteoarthritis of the knee after 10 to 13 wk of treatment (Wang 2015b **Level I**, 3 RCTs, n=1,011) (2 RCTs overlap). Therefore, duloxetine is a recommended treatment in updated guidelines for osteoarthritis (eg McAlindon 2014 **GL**).

Currently the use of antidepressants for acute neuropathic pain is mainly based on extrapolation of the above data. Clinical experience in chronic pain suggests that TCAs should be started at low doses (eg amitriptyline 5 to 10 mg at night) and subsequent doses increased slowly if needed, in order to minimise the incidence of adverse effects.

KEY MESSAGES

1. In chronic neuropathic pain and fibromyalgia, tricyclic antidepressants and serotonin–noradrenaline-reuptake inhibitor are effective analgesics (**W**) and more effective than selective serotonin-reuptake inhibitors (**U**) (**Level I** [Cochrane Review]).
2. Tricyclic antidepressants are effective in the treatment of chronic headaches (**U**) (**Level I** [PRISMA]).
3. Duloxetine is as effective as other first-line treatments for pain and disability of osteoarthritis (**U**) (**Level I**).
4. Some antidepressants, in particular duloxetine, may be effective in the treatment of chronic low-back pain (**U**) (**Level I**).
5. Perioperative serotonin-noradrenaline reuptake inhibitors reduce acute pain and opioid requirements in a limited number of studies (**U**) (**Level II**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Based on the experience in chronic neuropathic pain states, it would seem reasonable to use tricyclic antidepressants and serotonin–noradrenaline-reuptake inhibitors in the management of acute neuropathic pain (**U**).

☑ To minimise adverse effects, it is advisable to initiate treatment with tricyclic antidepressants at low doses (**U**).

4.8 | Anticonvulsant medicines

4.8.1 | Acute pain

4.8.1.1 | Alpha-2-delta ligands (gabapentinoids)

Efficacy

Gabapentin 250 mg as the sole analgesic reduces the intensity of postoperative pain (NNT 11; 95%CI 6.4 to 35) and requirements for rescue analgesia (NNT 5.8) vs placebo (Straube 2010 **Level I** [Cochrane], 4 RCTs, n=387). This is the only anticonvulsant which has been shown to be effective in acute postoperative pain on its own; the high NNT, inferior to most analgesics used in this setting, suggests that gabapentin is clinically not useful as a sole analgesic for postoperative analgesia.

Single 100 to 1200 mg and multiple 900 to 2400 mg/d doses of gabapentin (similar to pregabalin [see below]) reduce 24 h opioid consumption (MD -7.31 mg; 95%CI -9.74 to -5.98) (73 RCTs, n=5,630), but less so when analysing only RCTs with a low risk of bias (MD -3.1 mg; 95%CI -5.6 to -0.5) (13 RCTs, n=1,362) (Fabritius 2016 **Level I** [PRISMA], 132 RCTs, n=9,498). The opioid-sparing effect is not significant as an add-on to other non-opioids in trials with low risk of bias; in these the risk of serious adverse events (SAEs) is not significantly increased (RR 1.61; 95%CI 0.91 to 2.86). Similar results were found in an earlier meta-analysis of all RCTs of prophylactic gabapentin with an opioid-sparing effect in the first 24 h (8.44 mg; 95%CI 7.26 to 9.62) and reduced postoperative pain scores at multiple time points between 1 and 24 h by 0.71/10 to 1.68/10 (Doleman 2015a **Level I**, 133 RCTs, n=8,655) (significant overlap). These effects increased with increasing pain scores in the control group suggesting more benefit in more painful surgeries. The analysis also identified reduced pre-operative anxiety, postoperative nausea, vomiting and pruritus, and increased patient satisfaction, but also increased sedation. The authors acknowledge that the absolute effects may be overestimated by publication bias and small study effects.

Single 50 to 300 mg and multiple 100 to 600 mg/d doses of pregabalin for postoperative analgesia reduce 24 h IV morphine consumption (MD 10.8 mg; 95%CI –13.19 to –8.46) (37 RCTS, n=2,423) across all RCTs assessing this outcome, but less so when analysing only RCTs with a low risk of bias (MD 5.8 mg; 95%CI -8.5 to -3.2) (11 RCTs, n=705) (Fabritius 2017 **Level I** [PRISMA], 97 RCTs, n=7,201). In low risk of bias studies, the opioid sparing effect is more pronounced when no other non-opioids are used (MD -13.7 mg; 95%CI -9.6 to -17.8) (2 RCTs, n=120) and for single dose (MD -10.1mg; 95% CI -2.4 to -18.0) (6 RCTs, n=399) more so than with multiple dosing (MD 2.4mg; 95%CI -0.5 to -4.9) (5 RCTs, n=306).

In a preceding meta-analysis, operations were classified by the authors according to association with 'pronociceptive' mechanisms (acute hyperalgesia) (eg spine surgery, joint arthroplasty, amputations) and those without such mechanisms (eg abdominal laparoscopic surgery, gynaecological procedures) (Eipe 2015 **Level I** [PRISMA], 43 RCTs, n=3,378) (39 RCTs overlap). Pregabalin 150 to 300 mg reduces pain at rest and on movement more in the pronociceptive surgical group than in the other surgical group (MD -1.09/10; 95%CI -0.37 to -1.80 vs MD -0.45/10; 95%CI 0.13 to -1.03 and MD -0.94/10; 95%CI -0.65 to -1.23 vs MD -0.31/10; 95%CI 0.15 to -0.77). Across all RCTs, there is a reduction of mean analgesic consumption by 16% (pooled ratio of means 0.84; 95%CI 0.79 to 0.91). PONV is reduced (NNT 11; 95%CI 7 to 28).

Multiple meta-analyses have looked at perioperative gabapentin and pregabalin (single and multiple doses) in specific types of surgery with significant overlap with the overarching meta-analyses described above:

- In breast cancer surgery, preoperative use of gabapentin or pregabalin reduces acute postoperative pain and opioid consumption with low to very low quality of evidence of no effect on the rate of CPSP (Rai 2017 **Level I** [PRISMA], 12 RCTs, n=516);
- After open hysterectomy, gabapentin reduces postoperative opioid consumption and pain scores (Li 2017d **Level I** [PRISMA], 14 RCTs, n=879);
- After Caesarean section, gabapentin improves pain scores on movement at 24 h (MD -11.58/100; 95%CI -23.04 to -0.12) and increases satisfaction scores, with no other benefits (Felder 2019 **Level I** [PRISMA], 6 RCTs, n=656);
- After spinal surgery, gabapentin reduces pain scores and morphine consumption over the first 24 h (Han 2017a **Level I** [PRISMA], 10 RCTs, n=827);
- After laparoscopic cholecystectomy, gabapentin decreases analgesic requirements, pain scores and PONV (Sun 2016 **Level I** [PRISMA] 12 RCTs, n=1,192); pregabalin in the same setting has similar effects, except no effect on PONV (Zhang 2017c **Level I** [PRISMA], 6 RCTs, n=434);
- After TKA and THA, a number of meta-analyses with significant overlap are published:
    - After TKA and THA, pregabalin reduces pain scores, opioid consumption and PONV (Li 2017b **Level I** [PRISMA], 7 RCTs, n=823);
    - Specifically in TKA, meta-analyses identify similar benefits with pregabalin reducing opioid requirements and PONV and pruritus, but not pain scores (Han 2017b **Level I** [PRISMA], 7 RCTs, n=962) and gabapentin reducing opioid requirements and pruritus (Han 2016 **Level I** [PRISMA], 6 RCTs, n=859);
    - Specifically in THA, gabapentin reduces pain scores and opioid requirements, but no effect on any adverse effect (Han 2016 **Level I** [PRISMA] 5 RCTs, n=573). Pregabalin 150 mg preoperatively and 75 mg BD postoperatively for 7 d reduced pain and opioid requirements for 7 d with no effects on pain or physical function at 6 wk or 3 mth (Clarke 2015 **Level II**, n=184, JS 5);
    - A combined meta-analysis on the effects of pregabalin and gabapentin found only clinically insignificant reductions of pain (pregabalin only) at 24 h (0.5/10; 95%CI 0 to 1.0) and at 48 h (0.3/10; 95%CI 0 to 0.6) and a reduction in cumulative opioid consumption at 48 h (MD -23.2mg; 95%CI -40.9 to -5.4mg); the latter effect was only significant with pregabalin (MD -33.14 mg; 95%CI -53.98 to -12.29mg) There was no difference in knee flexion at 48 h, but a reduction in the incidence of PONV (RR 0.7; 95%CI 0.6 to 0.9) and an increase in the risk of sedation (only with pregabalin) (RR 1.4; 95% CI 1.1 to 1.9) (NNH 8.7) (Hamilton 2016 **Level I** [PRISMA], 12 RCTs, n=1,493) (4 RCTs [gabapentin] overlap with Han 2016 and all 7 RCTs [pregabalin] overlap with Han 2017b).

Used as an adjunct to epidural analgesia, perioperative gabapentin reduced pain scores and epidural analgesic requirements and improved patient satisfaction, despite an increase in dizziness (Turan 2006 **Level II**, n=54, JS 5) but these benefits were not confirmed with thoracic epidural analgesia for thoracotomy (Kinney 2012 **Level II**, n=120, JS 5).

Alpha-2-delta ligands were also studied in the setting of acute burns pain (see Section 8.5.2), acute herpes zoster pain (see Section 8.6.2.2) and acute pain due to Guillain-Barre Syndrome (see Section 8.10.6.7).

The effects of alpha-2-delta ligands on the prevention of CPSP are presented in Section 1.4.6.3.

Dose dependency of effect

A network meta-analysis reports a dose-dependent effect of single-dose preoperative pregabalin and gabapentin on reduction of pain scores and opioid consumption vs placebo (Hu 2018a **Level I**

[NMA], 79 RCTs, n=6,201). With regard to pain reduction, pregabalin in a dose ≥150mg and gabapentin ≥900 mg are more effective.

Effects on PONV

In RCTs designed with PONV as a primary endpoint (8 RCTs, n=838), preoperative gabapentin reduces PONV (RR 0.60; 99%CI 0.50 to 0.72), nausea (RR 0.34; 99%CI 0.20 to 0.56), and vomiting (RR 0.34; 99%CI 0.19 to 0.61) at 24 h (Grant 2016b **Level I** [PRISMA], 44 RCTs, n=3,489). These findings are similar in an analysis of all 44 RCTs; this is accompanied by an increased rate of sedation (RR 1.22; 95%CI 1.02 to 1.47).

In RCTs designed to report PONV, preoperative pregabalin reduces PONV (RR 0.53; 95%CI 0.39 to 0.73), nausea (RR 0.62; 95%CI 0.46 to 0.83), and vomiting (RR 0.68; 95%CI 0.52 to 0.88) at 24 h (Grant 2016a **Level I** [PRISMA], 23 RCTs, n=1,693). There is no increased sedation reported (RR 0.97; 95%CI 0.71 to 1.33), but an increase of postoperative visual disturbance (RR 3.11; 95%CI 1.34 to 7.21).

Adverse effects

Serious adverse effects (SAEs) in the studies with low risk of bias were rare (22/730) and occurred more with pregabalin than placebo (RR 2.9; 95%CI: 1.2 to 6.8); nausea, sedation and headache were not significantly different between the groups (Fabritius 2017 **Level I** [PRISMA], 97 RCTs, n=7,201).

Adverse effects of perioperative pregabalin include somnolence (RR 1.72; 95%CI 1.08 to 2.72), sedation (RR 1.51; 95%CI 1.16 to 1.96; absolute risk 41/1,000) and visual disturbances (RR 3.08; 95%CI 1.91 to 4.96; absolute risk 10/1,000) (Eipe 2015 **Level I** [PRISMA], 43 RCTs, n=3,378) (39 RCTs overlap). These adverse effects must be weighed against the benefits, which might not be clinically relevant in all postoperative settings. They may also compromise enhanced recovery strategies as outlined in ERAS guidelines eg for elective colorectal surgery (Gustafsson 2019 **GL**).

Toxicity

Overdose toxicity from gabapentin or pregabalin alone is rarely fatal, but the risk is increased when taken in combination with other agents that cause sedation, particularly opioids (then leading to OIVI). Another contributing factor to the interaction with opioids may be that pregabalin reversed the tolerance to opioids (Lyndon 2017 **BS**).

After laparoscopic surgery, preoperative gabapentin (300 to 600 mg) use as a component of multimodal analgesia increased the risk of respiratory depression in general (OR 1.47; 95% CI 1.22 to 1.76) (Cavalcante 2017 **Level III-3**, n=8,567 [n=1,311 episodes of respiratory depression]). In combination with systemic opioids in particular, the risk of OIVI was increased (OR 1.26; 95%CI 1.02 to 1.58) (n=965), in particular in older patients (>50 y) or those having received higher opioid doses. After joint arthroplasty, preoperative gabapentin (>300 mg) increased the risk of respiratory depression (Weingarten 2015 **Level IV**, n=11,970 [n=2,836 episodes of respiratory depression]). Use of alpha-2-delta ligands in combination with opioids was a risk factor for increased need for naloxone administration in hospital patients (Minhaj 2020 **Level III-2**, n=867 [n=275 naloxone administrations; n=105 alpha-2-delta ligand exposures]; Weingarten 2015 **Level III-2**, n=134 [naloxone administrations; n=15 alpha-2-delta ligand exposures]). This was also shown in patients after colorectal surgery (OR 1.58; 95%CI 1.11 to 2.26) despite an opioid-sparing effect (Ohnuma 2019 **Level III-**2; n=175,787 [4,677 alpha-2-delta ligand exposures]). Continuation of alpha-2-delta ligands into the postoperative period in patients receiving this therapy chronically was associated with increased need for naloxone administration (RR 6.30; 95%CI 2.4 to 16.7) but not in those receiving this as a new postoperative intervention (Deljou 2018 **Level III-2**, n=110,019 [n=128 naloxone administrations; n=39 alpha-2-delta ligand exposure). However, in a further study in hospitalised patients receiving opioids (where >60% received opioid for acute pain treatment only and 17% had surgery in the preceding 24 h), alpha-2-delta ligand use vs non-

use did not increase frequency of naloxone requirement (Savelloni 2017 **Level III-2**, n=128 [n=153 naloxone administrations; n=36 alpha-2-delta exposures]).

Data from many countries (USA, UK, Germany, Finland, India, South Africa and France) show that over 75% of deaths attributable to alpha-2-delta ligands also involve opioids (Smith 2016 **Level IV SR**, 34 studies & 23 case reports, n unspecified). This is in line with findings that the combination of gabapentin and opioid vs opioid alone increased the risk of opioid overdose death (OR 1.99; 95%CI 1.61 to 2.47) (Gomes 2017 **Level III-2**, n=5,875).

The combination of alpha-2-delta ligands with conventional opioids in postoperative patients may be associated with an increased risk of OIVI, in particular in certain patient subgroups (chronic users, obese patients, patients with OSA, older patients, higher dosing of opioids and/or alpha-2-delta ligands, combinations with other sedating medications). This is in line with warnings by regulatory authorities (FDA 2019 **GL**; MHRA 2017 **GL**). More data is required to delineate their role in ERAS and multimodal analgesic protocols (Gupta 2018b **NR**).

Abuse potential

Alpha-2-delta ligands have a potential for misuse, abuse and toxicity in overdose (Evoy 2017 **Level IV SR** [PRISMA], 59 studies [24 epidemiological, 3 clinical abuse liability, 16 case series or reports of abuse or misuse or dependence, 17 case series or reports of acute overdose]; Bonnet 2017 **Level IV SR** [PRISMA], 106 studies [17 rewarding behaviour, 14 clinical, 38 case series or reports on abuse and dependence, 37 on overdose toxicity or fatalities]; Schjerning 2016 **Level IV SR** [PRISMA], 76 studies [pregabalin only] [17 preclinical, 19 clinical, 13 epidemiological, 27 case series or reports]) (all with significant overlap of studies). Preclinical studies suggest that modulation of the GABA and glutamate systems, with resulting anxiolysis and in particular euphoria, underpin the abuse potential. The prevalence of abuse in the UK general population is 1.1% for gabapentin and 0.5% for pregabalin; consistently patients with opioid use disorder have higher rates: gabapentin 15 to 22% and pregabalin 3 to 68%. Substance use disorder and psychiatric comorbidities are the most important risk factors. Abuse typically involves the intake of supratherapeutic doses to achieve euphoria, with pregabalin appearing more addictive than gabapentin.

4.8.1.2 | Sodium valproate

A single dose of sodium valproate IV did not improve acute nociceptive pain after surgery (Martin 1988 **Level II**, n=39, JS 3). There are conflicting results on IV sodium valproate in treating acute migraine; it was ineffective in one study (Tanen 2003 **Level II**, n=40, JS 2) and superior to metoclopramide plus sumatriptan in another (Bakhshayesh 2013 **Level II**, n=60, JS 3).

4.8.2 | Chronic pain

Among all anticonvulsants, there is good evidence only for the use of alpha-2-delta ligands in chronic pain conditions including neuropathic pain states such as diabetic polyneuropathy, postherpetic neuralgia and central neuropathic pain as well as fibromyalgia (Wiffen 2013b **Level I** [Cochrane], 91 RCTs, n=17,995). For most other anticonvulsants, the evidence was non-existent, so little or of so low quality that conclusions could not be drawn, or of reasonable quality showing no or very little effect. This is in line with treatment guidelines for chronic neuropathic pain which recommend alpha-2-delta ligands, but no other anticonvulsants, as first-line treatment in this indication (Finnerup 2015 **GL Level I** [PRISMA], 229 RCTs, n unspecified).

4.8.2.1 | Alpha-2-delta ligands (gabapentin/pregabalin)

Gabapentin

At doses of 1,800 mg to 3,600 mg/d, gabapentin is effective in treating neuropathic pain, in particular caused by postherpetic neuralgia (NNT 6.7; 95%CI 5.4 to 8.7) (8 RCTs, n= 2,260) and diabetic polyneuropathy (NNT 5.9; 95% CI 4.6 to 8.3) (6 RCTs, n=1,277) (Wiffen 2017a **Level I** [Cochrane], 37 RCTs, n=5,914). Withdrawals due to adverse events were more common with gabapentin (NNH 30; 95%CI 20 to 65) (22 RCTs, n=4,346), while serious adverse events were not more common with gabapentin than with placebo. Pain relief in 20 to 40% of patients is accompanied by improvement of sleep, fatigue, depression, quality of life and function.

Gabapentin was also effective for the treatment of neuropathic pain caused by traumatic or postsurgical nerve injury (Gordh 2008 **Level II,** n=120, JS 5).

Pregabalin

Pregabalin is effective in a dose-dependent fashion in postherpetic neuralgia, painful diabetic neuropathy, central neuropathic pain due to spinal cord injury (SCI) and mixed or unclassified post-traumatic neuropathic pain, but only with limited evidence in neuropathic back pain or sciatica, neuropathic cancer pain or polyneuropathy and no effect in HIV neuropathy (2 RCTs, n=674) (Derry 2019 **Level I** [Cochrane], RCTs=45, n=11,906):

- Postherpetic neuralgia: 300 mg/d pregabalin (NNT 5.3; 95%CI 3.9 to 8.1) (4 RCTs, n=713) and 600 mg/d (NNT 3.9; 95%CI 3.1 to 5.5) (4 RCTs, n=732);
- Painful diabetic neuropathy: 600 mg/d pregabalin (NNT 7.8; 95% CI 5.4 to 14) (5 RCTs, n=1,015);
- Mixed or unclassified post-traumatic neuropathic pain: 600 mg/d pregabalin (NNT 7.2; 95%CI 5.4 to 11) (4 RCTs, n=1,367);
- Central neuropathic pain (mainly SCI): 600 mg/d pregabalin (NNT 9.8; 95%CI 6.0 to 28) (3 RCTs, n=562).

In all studies, somnolence and dizziness occurred more in pregabalin than placebo arms in a dose-dependent pattern, but serious adverse events were not different between arms: pregabalin 300 mg (RR 1.2; 95%CI 0.8 to 1.7) (17 RCTs, n=4,112) and pregabalin 600 mg (RR 1.1; 95%CI 0.8 to 1.5) (16 RCTs, n=3,995).

Pregabalin 300 to 600 mg/d has also beneficial effects in fibromyalgia; substantial pain relief is achieved over 12 to 26 wk of treatment in about 10% more patients than in the placebo arm, accompanied by improvements of other symptoms, quality of life and function (Derry 2016a **Level I** [Cochrane], 8 RCTs, n=3,283).

Alpha-2-delta ligands are also used in chronic pain due to SCI (see Section 8.2.2.5), phantom limb pain (see Section 8.1.5.2) and in patients who are opioid-tolerant (see Section 9.7) or have a substance use disorder (see Section 9.8).

4.8.2.2 | Carbamazepine

Carbamazepine for the treatment of chronic neuropathic pain has possibly some analgesic efficacy in some patients, but the quality of data is insufficient to draw meaningful conclusions or make comparisons (Wiffen 2014 **Level I** [Cochrane], 10 RCTs, n=480).

4.8.2.3 | Oxcarbazepine

Only very-low level evidence supports limited effectiveness of oxcarbazepine in painful diabetic neuropathy, neuropathic pain from radiculopathy and a mixture of neuropathies (Zhou 2017 **Level I** [Cochrane], 5 RCTs, n=862).

4.8.2.4 | Phenytoin

No study supports the use of phenytoin in chronic neuropathic pain or fibromyalgia (Birse 2012 **Level I** [Cochrane], 0 RCTs, n=0).

4.8.2.5 | Valproate

Valproate may reduce pain in diabetic polyneuropathy based on very small RCTs of poor quality (Gill 2011 **Level I** [Cochrane] 2 RCTs, n=84). Valproate is effective for the prevention of episodic migraine (Linde 2013 **Level I** [Cochrane], 10 RCTs, n=652).

4.8.2.6 | Lamotrigine

Lamotrigine shows no analgesic benefit in neuropathic pain in large, high-quality, long-duration RCTs (Wiffen 2013a **Level I** [Cochrane] 12 RCTs, n=1,511).

4.8.2.7 | Lacosamide

Lacosamide is not beneficial for the treatment of neuropathic pain and fibromyalgia (Hearn 2012 **Level I** [Cochrane] 6 RCTs, n=2,022).

KEY MESSAGES

1. Alpha-2-delta ligands (gabapentinoids) are the only anticonvulsants with proven efficacy in the treatment of chronic neuropathic pain (**S**) (**Level I** [Cochrane Review]).
2. Pregabalin is the only anticonvulsant with proven but limited efficacy in chronic pain due to fibromyalgia (**S**) (**Level I** [Cochrane Review]).
3. Perioperative alpha-2-delta ligands (gabapentinoids) reduce postoperative pain and opioid requirements, in particular after more painful surgery (**Q**) and reduce the incidence of postoperative nausea and vomiting (**S**) as well as pruritus (**S**), but increase the risk of sedation (**S**) and visual disturbances (**N**) (**Level I** [PRISMA]).
4. Overdose toxicity of alpha-2-delta ligands is increased when taken in combination with other agents that cause sedation, particularly opioids (**N**) (**Level III-2**).
5. Alpha-2-delta ligands have the potential for misuse and abuse, in particular in patients with opioid use disorder or psychiatric comorbidity (**N**) (**Level IV SR**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Based on the experience in chronic neuropathic pain states, it would seem reasonable to use alpha-2-delta ligands in the management of acute neuropathic pain (**U**).

4.9 | Alpha-2 agonists

4.9.1 | Systemic alpha-2 agonists

4.9.1.1 | Clonidine

Clonidine is a selective alpha-2 agonist with an alpha-2 to alpha-1 ratio of 200:1 (Chan 2010a **NR**). Systemic perioperative administration of clonidine 1 to 5 mcg/kg vs placebo does not reduce pain scores, but has an opioid-sparing effect at 24 h (MD 24%; 95%CI 16 to 32) (4 RCTs, n=313) and reduces incidence of PONV (RR 0.35; 95%CI 0.25 to 0.51]) (6 RCTs, n=412) (Sanchez Munoz 2017 **Level I** [PRISMA], 57 RCTs, n=14,790 [PO 29 arms, IM 4 arms, IV 24 arms, TD 2 arms]).

After non-cardiac surgery, PO clonidine 200 mcg given preoperatively and continued as 200 mcg/d transdermal clonidine patch for 72 h did not reduce pain scores or opioid consumption vs placebo over these 72 h (Turan 2016 **Level II**, n=624, JS 5). An updated meta-analysis adding this and two further RCTs to a preceding one (Blaudszun 2012 **Level I** [PRISMA], 30 RCTs [clonidine 19 RCTs], n=1,792 [clonidine n=1,156]) confirms no effect of clonidine vs placebo on pain scores at 24 h (7 RCTs, n=802) or 48 h (4 RCTs, n=562) (Turan 2016 **Level I**, 7 RCTs, n=802).

Alpha-2 agonists such as clonidine are more effective than placebo in the management of opioid-withdrawal symptoms (Gowing 2014 **Level I** [Cochrane], 25 RCTs, n=1,668).

4.9.1.2 | Dexmedetomidine

Dexmedetomidine is a highly selective alpha-2 adrenoceptor agonist with an alpha-2 to alpha-1 ratio of 1,620:1 (Chan 2010a **NR**). Systemic intraoperative only administration of dexmedetomidine vs placebo reduces pain intensity at 6 h (WMD −0.93/10; 95%CI −1.34 to −0.53) and at 24 h (WMD=−0.47/10; 95%CI −0.83 to −0.11) as well as opioid consumption (WMD −6.76 mg; 95% CI −10.16 to −3.35) (Wang 2018c **Level I** [PRISMA], 40 RCTs, n=2,401). Dexmedetomidine also reduces the need for rescue analgesia (7 RCTs, n=290) and extends the time to first rescue analgesia (4 RCTs, n=220), without impact on PONV (5 RCTs, n=262). Dexmedetomidine used perioperatively (12 RCTs [intraoperative use only]) in spinal surgery reduces postoperative pain at 2 h postoperatively and reduces analgesic requirement at 12 h (2 RCTs) and 48 h (3 RCTs), but not 24 h (3 RCTs) (Tsaousi 2018 **Level I** [PRISMA], 15 RCTs, n=913) (4 RCTs overlap).

Findings in paediatric RCTs are similar, see Section 10.4.8.

4.9.1.3 | Effects of systemic dexmedetomidine on neuraxial and peripheral blocks

The use of IV dexmedetomidine in patients receiving spinal anaesthesia prolongs time to first analgesic request by at least 60% as well as duration of sensory and motor block by 34% respectively 17% (Abdallah 2013 **Level I** [PRISMA], 7 RCTs, n=364). These results were in principle confirmed by a subsequent systematic review, which separately analysed 8 RCTs published since the previous review (Johnson 2016 **Level I**, 8 RCTs, n=480) and by one subsequent RCT (Kumari 2017 **Level II**, n=60, JS 5). Most of the RCTs utilised an initial bolus dose and a subsequent maintenance infusion for the duration of surgery (11 of the overall 16 RCTs). IN dexmedetomidine had a significant opioid-sparing effect after THA (Uusalo 2019 **Level III-3**, n=120).

IV dexmedetomidine 0.5 mcg/kg but not IV midazolam prolonged spinal bupivacaine sensory block and also provided sedation and additional analgesia in patients undergoing transurethral resection of the prostate (Kaya 2010 **Level II**, n=75, JS 2).

IV dexmedetomidine 2 mcg/kg significantly prolonged analgesia and reduced postoperative

opioid requirements after single-shot interscalene brachial plexus block vs placebo and lower doses of dexmedetomidine (0.5 and 1 mcg/kg) (Kang 2018a **Level II**, n=72, JS 5).

See also Sections 4.9.2.1 and 4.9.2.2 below.

KEY MESSAGE

1. Alpha-2 agonists such as clonidine are more effective than placebo in the management of opioid-withdrawal symptoms (**U**) (**Level I** [Cochrane Review]).
2. The perioperative use of clonidine systemically (excluding transdermal administration) does not reduce pain intensity (at 24 or 48 hours) (**Q**) (**Level I**) but reduces opioid consumption and postoperative nausea and vomiting versus placebo (**Q**) (**Level I** [PRISMA]).
3. The perioperative use of the systemic dexmedetomidine reduces postoperative pain intensity, opioid consumption and requirements for rescue analgesia (**S**) without effect on postoperative nausea and vomiting (**N**) (**Level I** [PRISMA]).
4. The IV administration of dexmedetomidine combined with intrathecal local anaesthetic prolongs time to first analgesic request (**N**) (**Level I** [PRISMA]).

4.9.2 | Regional alpha-2 agonists

Alpha-2 adrenoceptor agonists act as an analgesic at the level of the dorsal horn of the spinal cord, although there may be peripheral effects as well (Chan 2010a **NR**). Systemic adverse effects are predominantly centrally mediated sedation and hypotension.

4.9.2.1 | Neuraxial

Clonidine

There is no human or animal evidence of neurotoxicity when preservative-free clonidine is administered IT (Hodgson 1999 **NR**). Epidural clonidine is approved by the FDA for relief of chronic cancer pain.

In volunteers, significant analgesia to experimental heat pain was detected with IT doses >25 mcg clonidine: with 50 mcg having similar effects on heat threshold to 5 mg bupivacaine (Ginosar 2013 **Level II EH**, n=11, JS 4). IT clonidine given in doses from 15 to 150 mcg, combined with IT local anaesthetic does not affect the rate of onset of a local anaesthetic block, but significantly prolongs the time to two-segment block regression and prolongs the time to first analgesic request (median 101 min, range 35–310 min) (Elia 2008 **Level I**, 22 RCTs, n=1,445). Treatment effects were noted to be heterogeneous and dose responsiveness could not be demonstrated. IT clonidine also reduces intraoperative pain, but hypotension was more frequent (RR 1.8; 95%CI 1.4 to 2.3) (Elia 2008 **Level I**, 22 RCTs, n=1,445).

The addition of IT clonidine to IT morphine causes a small increase in duration of analgesia (MD 1.63 h; 95%CI 0.93 to 2.33) and reduced the amount of systemic morphine consumption over 24 h (MD 4.45 mg; 95%CI -1.40 to -7.49) (Engelman 2013 **Level I**, [PRISMA], 7 RCTs, n=503). Hypotension is also increased (OR 1.78; 95%CI 1.02 to 3.12).

IT clonidine 30 to 150 mcg as an adjuvant to neuraxial anaesthesia during Caesarean section prolongs the duration of sensory block (MD 128 min; 95%CI 82 to 175) and motor block (MD 45 min; 95%CI 9 to 81) (Crespo 2017 **Level I** [PRISMA], 12 RCTs, n=1,280). IT clonidine increases sedation (RR 3.92; 95%CI 1.17 to 13.14), but does not increase the risk of hypotension, affect

pruritus or PONV. Neuraxial clonidine 50 to 150 mcg (epidural and IT) modestly enhances postoperative analgesia in women having Caesarean section under neuraxial anaesthesia (Allen 2018 **Level I** [PRISMA], 12 RCTs [IT administration] [9 RCT overlap with Crespo 2017] & 6 RCTs [epidural administration: 2 RCTs bolus followed by infusion, 2 RCTs repeated bolus, 2 RCTs single bolus], n=1,169). Neuraxial clonidine reduces morphine consumption (MD -8.7 mg; 95% CI -15.3 to -2.0); this effect is less with IT administration (MD -4.3 mg; 95%CI -7.0 to -1.5) than with epidural administration (MD -18.9 mg; 95%CI -34.8 to -3.0). It also increases the time to first analgesic request (MD 150 min; 95%CI 110 to 190) vs placebo, but does not improve pain scores on movement at 0 to 6 h. Neuraxial clonidine increases the risk of intraoperative hypotension (49%) vs placebo (33%) and of intraoperative sedation. Risks for bradycardia, nausea/vomiting and pruritus are inconclusive. There was no case of respiratory depression and neonatal outcome was not different in control and study group.

In obstetrics patients, the time to achieve highest sensory and complete motor block was less and duration of analgesia was longer when clonidine and hyperbaric bupivacaine were administered sequentially, compared to the mixing of the two medicines in a single syringe (Sachan 2014 **Level II**, n=60, JS 4).

Low-dose infusion of clonidine alone via thoracic epidural catheters after spinal surgery reduced systemic opioid requirements and nausea without causing significant sedation or hypotension (Farmery 2009 **Level II**, n=65, JS 5). The addition of clonidine to PCEA with ropivacaine and morphine after TKA decreased opioid requirements and improved analgesia without increasing adverse effects (Huang 2007 **Level II**, n=80, JS 3). The addition of clonidine to epidural anaesthesia with ropivacaine after haemorrhoidectomy improved analgesia without causing adverse effects (Baptista 2014 **Level III-2**, n=80).

Dexmedetomidine

Dexmedetomidine is not approved for epidural or IT administration and animal studies on its neurotoxicity via these routes are contradictory (Ozdamar 2018 **BS**; Konakci 2008 **BS**).

Epidural single-shot dexmedetomidine 0.5 to 1.5 mcg/kg as an adjuvant to epidural analgesia prolongs analgesia (SMD 3.50 h; 95%CI 1.86 to 5.13) (8 RCTs) and reduces rescue analgesia requirements (SMD -2.00; 95% CI -2.80 to -1.21) (6 RCTs) and pain scores (SMD -0.76; 95%CI -1.46 to -0.06) (4 RCTs) (Zhang 2017b **Level I** [PRISMA]; 12 RCTs, n=660). It increases sedation scores and reduces heart rate minimally with no other significant adverse effects, and reduces postoperative shivering. Pain relief was improved with 0.5 mcg/kg epidural dexmedetomidine versus 0.5 mcg/kg IV administration for open thoracotomy (Zeng 2017 **Level II**, n=73, JS 5).

IT dexmedetomidine 3 to 100 mcg vs IT clonidine 30 mcg to 2 mcg/kg as adjuvants for IT local anaesthetics results in a minor prolongation of the sensory block (WMD 24.2 min; 95%CI 12.8 to 35.6) and a prolongation of time to first analgesic request (WMD 65.8 min; 95%CI 14.7 to 116.9) with no difference in incidence of adverse effects (Zhang 2016 **Level I** [QUOROM], 7 RCTs, n=354).

IT dexmedetomidine 3 to 10 mcg vs IT fentanyl 15 to 25 mcg prolongs the pain free period (SMD 2.98 h; 95%CI 1.69 to 4.27) without increasing the incidence of adverse events, including hypotension and bradycardia (Sun 2017b **Level I**, 9 RCTs, n=639). Similarly, after lower limb orthopaedic surgery, the addition of IT dexmedetomidine 5 mcg vs IT fentanyl 25 mcg to IT bupivacaine significantly prolonged duration of sensory, motor block and postoperative analgesia vs saline (Rahimzadeh 2018 **Level II**, n=90, JS 4). In patients undergoing lower limb surgery, IT dexmedetomidine 5 mcg was associated with prolonged motor and sensory block, haemodynamic stability and reduced demand of rescue analgesics at 24 h vs IT clonidine 30 mcg, fentanyl 25 mcg, or saline with bupivacaine (Mahendru 2013 **Level II**, n=60, JS 4).

In patients having lower abdominal surgery using IT bupivacaine 0.5%, IT dexmedetomidine 5 mcg vs IT buprenorphine 60 mcg prolonged anaesthesia and analgesia with a reduced need for

sedation and rescue analgesics (Gupta 2014 **Level II**, n=60, JS 5). Similarly, in patients undergoing lower abdominal surgery, the quality of anaesthesia was superior with low-dose bupivacaine/dexmedetomidine 5 mcg vs bupivacaine/fentanyl 25mcg (Nayagam 2014 **Level II**, n=150, JS 4). Dexmedetomidine facilitated the spread of the block and prolonged postoperative analgesia. For major abdominal cancer surgery, the addition of IT dexmedetomidine 5 mcg to IT morphine 500 mcg/bupivacaine did not improve analgesia vs IT morphine/bupivacaine (Abdel-Ghaffar 2016 **Level II**, n=90, JS 5). Both groups with adjuvants experienced better analgesia than bupivacaine alone.

Adrenaline (epinephrine)

Adding IT adrenaline to IT local anaesthetics (27 RCTs, n=1,660) prolongs motor block (WMD 64 min; 99%CI 37 to 91), analgesia (WMD 34 min; 99%CI 6 to 62) and time to 2 segments regression (WMD 20 min; 99%CI 11 to 28) (Tschopp 2018 **Level I** [PRISMA] [trial sequential analysis], 70 RCTs, n=3,644). For epidural analgesia (37 RCTs, n=1,781), no effects can be identified either due to lack of an effect (pain intensity, hypotension) or insufficient numbers (motor block, urinary retention). These findings are in line with those of a preceding meta-analysis which also presented dose dependent effects of IT adrenaline (de Oliveira 2012a **Level I** [PRISMA], 24 RCTs, n=1,271) (significant overlap). Doses of ≤100 mcg prolong sensory and motor block duration but are also associated with more hypotension and PONV than higher doses. IT adrenaline at doses >100 mcg prolongs sensory and motor block more than the lower dose but is not associated with a greater incidence of hypotension and PONV vs IT local anaesthetic alone. The effect of IT adrenaline in prolonging analgesia duration was not seen when added to IT local anaesthetic/opioid combinations (de Oliveira 2012a **Level I** [PRISMA], 24 RCTs, n=1,271).

The influence of caudal adrenaline and/or clonidine on the absorption characteristics of caudal levobupivacaine were evaluated in children (Chalkiadis 2013 **PK**, n=240). Adrenaline 5 mcg/mL decreased the rate of levobupivacaine systemic absorption, reducing peak concentrations by half. Clonidine 2 mcg/mL resulted in faster systemic absorption of levobupivacaine and a similar concentration time profile to levobupivacaine alone.

In postoperative thoracic epidural infusion, the addition of adrenaline to fentanyl and ropivacaine or bupivacaine improved analgesia (Niemi 2003 **Level II**, n=33, JS 5; Niemi 2002 **Level II**, n=12, JS 5; Sakaguchi 2000 **Level II**, n=77, JS 2). The efficacy of thoracic epidural pethidine infusions after thoracotomy was not improved by addition of adrenaline (Bryson 2007 **Level II**, n=50, JS 5).

With lumbar epidural infusions, no analgesic benefit was seen with added adrenaline at 2 mcg/mL or 4 mcg/mL (Forster 2008 **Level II,** n=63, JS 3; Forster 2003 **Level II**, n=46, JS 5).

In labour epidural analgesia, adrenaline 5 mcg/mL added to low-dose bupivacaine infusions decreased pain scores and resulted in longer redosing intervals with no change in labour duration (Connelly 2011 **Level II**, n=60, JS 4).

See also Section 5.7.1.4, for obstetric use Section 9.1.3.3 and for paediatric use Sections 10.4.8.1 and 10.6.3.3.

4.9.2.2 | Peripheral nerve block

Clonidine

A meta-analysis evaluated the benefits of clonidine as an adjuvant to local anaesthetics for various peripheral nerve and plexus blocks (Popping 2009 **Level I**, 20 RCTs, n=1,054). Clonidine doses ranged from 30 to 300 mcg with most patients receiving 150 mcg. Clonidine prolongs the duration of postoperative analgesia (WMD 122 min; 95%CI 74 to 169), sensory block (WMD 74 min; 95%CI 37 to 111) and also prolongs motor block. However, clonidine increases the risk of hypotension (OR 3.61; 95%CI 1.52 to 8.55), bradycardia (OR 3.09; 95%CI 1.10 to 8.64) and sedation (OR 2.28; 95%CI 1.15 to 4.51). There was a lack of evidence of dose-responsiveness for

beneficial or harmful effects. Subsequent studies in supraclavicular blocks report similar findings (Nasir 2017 **Level II**, n=97, JS 4; Chakraborty 2010 **Level II**, n=70, JS 4; Singh 2010 **Level II**, n=50, JS 4). However, the addition of 150 mcg clonidine to levobupivacaine 0.5% 20 mL in posterior gluteal (Labat) sciatic nerve block did not prolong the duration of analgesia and resulted in more hypotension vs the control group (Fournier 2012 **Level II**, n=60, JS 4).

In an experimental setting controlling for systemic effects of clonidine using bilateral adductor canal blocks, the addition of 150 mcg clonidine to ropivacaine for one side resulted in no difference in block characteristics (quality and duration) on either side (Andersen 2017 **Level II EH**, n=21, JS 5).

Evidence is lacking for the use of clonidine as an adjuvant to local anaesthetics for continuous catheter techniques, with no studies showing benefit (McCartney 2007 **Level I**, 3 RCTs [continuous], n=110).

Dexmedetomidine

Animal studies suggest potential dose-dependent neurotoxic effects when dexmedetomidine is combined with ropivacaine for 48 h of continuous FNB in rabbits (Wang 2019 **BS**) and for brachial plexus injection in high doses in rats (Kang 2018b **BS**).

Dexmedetomidine 25 to 150 mcg added to local anaesthetics for various peripheral nerve and plexus blocks increases duration of postoperative analgesia (MD 4.87 h; 95%CI 4.02 to 5.73) (Schnabel 2018 **Level I** [PRISMA], 46 RCTs, n=3,149). Dexmedetomidine increases the risk of intraoperative bradycardia (RR 2.83; 95%CI 1.50 to 5.33) and hypotension (RR 3.42; 95%CI 1.24 to 9.48). Perineural and IV administration of dexmedetomidine results in a similar prolongation of duration of analgesia (MD 0.98 h; 95%CI -0.12 to 2.08) (2 RCTs, n=107). However, for ulnar nerve blocks, perineural 100 mcg administration was superior to systemic dexmedetomidine in prolonging block duration: perineural 14.4 h (95%CI 13.1 to 15.6) vs systemic administration 9.2 h (95%CI 8.6 to 9.8) vs without dexmedetomidine 7.1 h (95%CI 6.6 to 7.6) (Andersen 2019 **Level II EH**, n=22, JS 5).

Meta-analyses of data on specific blocks have significant overlap with the overarching meta-analysis (Schnabel 2018 **Level I** [PRISMA], 46 RCTs, n=3,149) and show similar results:

- For thoracic paravertebral blocks (PVB), dexmedetomidine 1mcg/kg combined with local anaesthetics reduces pain at rest and with movement; for the latter the results were (SMD -1.63/10; 95%CI -2.92 to -0.34) and at 24 h (SMD -1.78/10; 95% CI -2.66 to -0.90) (Wang 2018a **Level I** [QUORUM], 7 RCTs [2 RCTs infusion, 5 RCTs single shot 1 mcg/kg], n=350). It extends duration of analgesia (202 min; 95% CI 33.5 to 369.6) and reduces postoperative analgesic consumption, while increasing the incidence of hypotension (OR 4.40; 95% CI 1.37 to 14.17);
- For TAPB, dexmedetomidine 0.5 to 1 mcg/kg as an adjuvant increases duration and quality of analgesia, while being opioid sparing (WMD −13.71; 95%CI −17.8 to −9.6) without increasing adverse effects (Sun 2019 **Level I** [PRISMA], 20 RCTs, n=1,212);
- As part of a brachial plexus block, perineural dexmedetomidine reduces time to onset of sensory and motor block, and prolongs sensory, motor block and analgesia duration by at least 57, 58 and 63% respectively (the latter by 266 min; 95%CI 191 to 343) (Vorobeichik 2017 **Level I** [PRISMA], 32 RCTs, n=2,007; Hussain 2017 **Level I**, 18 RCTs, n=1,092 [17 RCTs overlap]; Ping 2017 **Level I** [QUOROM], 18 RCTs, n=1,014 [10 RCTs overlap]). In addition, dexmedetomidine has an opioid sparing effect (MED 10.2 mg; 95%CI -15.3 to -5.2) in the first 24 h, improves pain control and enhances patient satisfaction, but increases the incidence of bradycardia and hypotension.

A dose-finding study for dexmedetomidine as an adjunct to interscalene brachial plexus block identified 2 mcg/kg as superior over 1 and 1.5 mcg/kg with regard to duration of analgesia

(placebo: 808 min ± 180; 1 mcg/kg: 1,033 min ± 288; 1.5 mcg/kg: 1,042 min ± 188; 2 mcg/kg: 1,224 min ± 238 min), but with an increased risk of hypotension for the two highest dose groups (Jung 2018 **Level II**, n=100, JS 5).

Compared with clonidine 1 to 2 mcg/kg, the perineural application of dexmedetomidine ≈1 to 2 mcg/kg as a local anaesthetic adjuvant in single-injection supraclavicular block produces significant prolongation of sensory block, motor block, and postoperative analgesia (on average by a factor of 1.2), while increasing the incidence of transient bradycardia (OR 7.4; 95%CI 1.3 to 40.8) and postoperative sedation (OR 11.8; 95%CI 1.9 to 73.6) (El-Boghdadly 2017 **Level I** [PRISMA], 14 RCTs, n=868).

Compared with dexamethasone 1 to 8 mg, dexmedetomidine 30 to 100 mcg as a perineural adjuvant for supraclavicular plexus block was inferior with regard to duration of analgesia (MD -148 min; 95%CI -259 to -37), while causing more hypotension (RR 6.3; 95%CI 1.5 to 27.5) and sedation (Albrecht 2019 **Level I** [PRISMA], 49 RCTs, n=3,019).

Adrenaline

Adrenaline added to local anaesthetics for locoregional anaesthesia (6 RCTs, n=203) prolongs analgesia (WMD 66 min; 98%CI 32 to 100) (Tschopp 2018 **Level I** [PRISMA] [trial sequential analysis], 70 RCTs, n=3,644).

For paediatric use see Section 10.6.2.6.

4.9.2.3 | Intravenous regional anaesthesia

Clonidine

Clonidine 150 mcg was inferior to magnesium sulphate (1.5 g of 50% MgSO4) as an adjuvant to IVRA with shorter time to first analgesic request (169.5 ± 33.3 vs 193.9 ± 38.4 min) and greater requirements for rescue analgesia (2.1 ± 0.8 vs 1.6 ± 0.7) (Kaur 2017 **Level II**, n=40, JS 5). Similarly, no analgesic benefit was found in a dose-finding study with clonidine (0 to 1.5 mcg/kg) added to IVRA (Ivie 2011 **Level II**, n=52, JS 5).

Dexmedetomidine

Addition of dexmedetomidine (most frequently 0.5 mcg/kg) to lidocaine or prilocaine IVRA increased duration and quality of analgesia (Subramanya 2017 **Level II**, n=60, JS 5; Kumar 2012 **Level II**, n=72, JS 5; Kol 2009 **Level II**, n=75, JS 5; Esmaoglu 2005 **Level II**, n=40, JS 4; Memis 2004 **Level II**, n=30, JS 4).

In patients having carpal tunnel repairs under IVRA, dexmedetomidine IV was compared with dexmedetomidine added to the local anaesthetic for IVRA and with placebo (Mizrak 2010 **Level II**, n=45, JS 5). Both routes of dexmedetomidine had similar effects, with improved postoperative pain scores up to 30 min.

Dexmedetomidine 1 mcg/kg vs midazolam (50 mcg/kg) as an adjuvant to IVRA resulted in similar duration of analgesia (Subramanya 2017 **Level II**, n=60, JS 4).

4.9.2.4 | Intra-articular

Clonidine

Intra-articular (IA) clonidine vs placebo after arthroscopic knee surgery reduces pain scores for 4 h, the need for rescue analgesia and postoperative nausea, but increases the risk of hypotension (Sun 2014 **Level I** [PRISMA] 7 RCTs, n=230). Combined femoral-sciatic nerve block offered better analgesia with fewer adverse effects than IA infiltration with bupivacaine/clonidine/morphine in children undergoing anterior cruciate ligament reconstruction (Tran 2005 **Level II**, n=36, JS 2).

Dexmedetomidine

IA dexmedetomidine 100 mcg when added to ropivacaine resulted in a longer time to analgesic request than ropivacaine alone (mean 10.8 h [SD 2.6] vs 5.4 h [SD 1.4]) (Paul 2010 **Level II**, n=30, JS 5). Compared with IV route, IA dexmedetomidine resulted in a longer time to first analgesia (IA 312.0 min [SD 120.7]; IV 102.1 min [SD 54.4]; placebo 71.0 min [SD 50.1]) (Al-Metwalli 2008 **Level II**, n=60, JS 5). When IA dexmedetomidine 100 mcg, fentanyl 50 mcg and ropivacaine each alone were compared following knee arthroscopy, time to first analgesia was longest with ropivacaine, followed by fentanyl and then dexmedetomidine (mean: 380 min [SD 22], 327 min [SD 17] and 244 min [SD 20] respectively) (Manuar 2014 **Level II**, n=99, JS 2). Added to bupivacaine, IA dexmedetomidine 1 mcg/kg resulted in similar prolongation and quality of analgesia as IA dexamethasone 8 mg vs bupivacaine alone after meniscal surgery (Moeen 2017 **Level II**, n=60, JS 5).

KEY MESSAGES

1. Neuraxial clonidine improves duration and quality of analgesia and is opioid sparing when used as an adjuvant to neuraxial local anaesthetics (in particular after Caesarean section) (**S**) (**Level I** [PRISMA]) or to morphine (**U**) (**Level I** [PRISMA]), but increases the risk of hypotension and sedation (**N**) (**Level I** [PRISMA]).
2. Neuraxial dexmedetomidine improves duration and quality of analgesia when used as an adjuvant to neuraxial local anaesthetics (**S**) (**Level I** [PRISMA]).
3. Intrathecal adrenaline (epinephrine) when combined with local anaesthetic, but not with intrathecal opioids, prolongs analgesia duration (**U**) (**Level I** [PRISMA]).
4. Dexmedetomidine when added to local anaesthetics for peripheral nerve blocks improves duration and quality of analgesia, but is associated with increased hypotension and bradycardia (**S**) (**Level I** [PRISMA]).
5. Intra-articular clonidine reduces pain scores for 4 hours, need for rescue analgesia and incidence of nausea, but increases hypotension (**N**) (**Level I** [PRISMA])
6. Clonidine improves duration of analgesia and anaesthesia when used as an adjuvant to local anaesthetics for peripheral nerve and plexus blocks but is associated with increased hypotension and bradycardia (**U**) (**Level I**).
7. Dexmedetomidine added to intravenous regional anaesthesia improves and prolongs analgesia (**U**) (**Level II**).
8. Epidural adrenaline (epinephrine) in combination with a local anaesthetic improves the quality of postoperative thoracic epidural analgesia (**U**) (**Level II**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ The benefits of perineural adjuvant administration of alpha-2-agonists over systemic administration remains unclear (**N**).

4.10 | Salmon calcitonin and bisphosphonates

4.10.1 | Calcitonin

Calcitonin is a 32-amino acid peptide hormone that regulates calcium homeostasis in vertebrates. It also has analgesic properties, primarily through receptor-mediated modulation of serotonergic activity in pain pathways of the CNS (Visser 2005 **NR**). Salmon calcitonin has a greater potency than mammalian forms of the hormone and is therefore reproduced as a synthetic medicine for pharmaceutical use. The adverse effects of calcitonin therapy such as sedation, nausea, skin flushing and diarrhoea may reflect increased serotonergic activity. In rodents, the $5HT_3$ antagonist tropisetron reduced its analgesic efficacy, which may be relevant in humans during the treatment of its adverse effects – nausea and vomiting (Visser 2005 **NR**).

In patients with osteoporotic vertebral compression fractures, salmon calcitonin (IV, SC, IM, IN or rectal) administered within <10 d reduces acute pain at rest and on movement within 1 wk and improves mobilisation (in 7 to 28 d); adverse effects are usually minor and mainly gastrointestinal (Knopp-Sihota 2012 **Level I** [PRISMA], 13 RCTs, n=589). Weekly IM injections of eel calcitonin (elcatonin 20 Units) were more effective than NSAIDs in controlling pain and improving mobility in new (<2 wk) thoracolumbar osteoporotic fractures (Endo 2017 **Level II**, n=228, JS 3). In chronic pain (>3 mth) from pre-existing osteoporotic vertebral compression fractures, the effect was minimal and only statistically significant on movement at 6 mth. In a case series, IN salmon calcitonin reduced pain due to fracture of the coccyx (Foye 2014 **Level IV**, n=8).

In acute phantom limb pain, IV (and likely SC) salmon calcitonin was more effective than placebo (Jaeger 1992 **Level II**, n=21 (cross over), JS 3; Bornemann-Cimenti 2017 **CR**; Turek 2012 **CR**). However, it was not effective for chronic phantom limb pain (Eichenberger 2008 **Level II**, n=20 [cross over], JS 5). While epidurally administered calcitonin reduced the incidence of chronic phantom limb pain, allodynia and hyperalgesia at 6 and 12 mth in diabetic patients undergoing lower limb amputation (Yousef 2017 **Level II**, n=60, JS 5).

In CRPS, a meta-analysis concluded that salmon calcitonin (IN, IV) is beneficial (Perez 2001 **Level I**, 5 RCTs [calcitonin], n=260). However, the only two placebo-controlled RCTs in this meta-analysis produced conflicting results. A subsequent RCT found that calcitonin was no more effective than paracetamol in improving pain and function in CRPS over a 2 mth period in patients already receiving physical therapy following upper limb trauma (Sahin 2006 **Level II**, n=35, JS 2). A network meta-analysis recommended short term (<2 mth) calcitonin by all routes of administration in CRPS over 12 mth in duration (Wertli 2014 **Level I** [NMA], 3 RCTs [calcitonin], n=116); the RCTs included did not use IASP or Budapest diagnostic criteria for CRPS and the quality of the data have been questioned by other authors (Benzon 2016 **NR**).

Neuropathic pain after SCI was responsive to SC salmon calcitonin (Humble 2011 **Level IV**, n=3).

In lumbar spinal stenosis, salmon calcitonin (IN, IM, SC) has no effect on pain or walking distance vs placebo or paracetamol regardless of method of administration (Peng 2015 **Level I**, 6 RCTS, n=232).

The limited evidence available does not support the effectiveness of SC salmon calcitonin in the treatment of acute and persistent metastatic bone pain (Martinez-Zapata 2006 **Level I** [Cochrane], 2 RCTs, n=90).

With long-term use of salmon calcitonin for treatment of chronic osteoporosis (with unproven efficacy), there is a suggested association with increased cancer incidence; however, this is based on studies with poor-quality cancer assessment methodology (Overman 2013 **NR**). A subsequent meta-analysis further weakened the association and found little biological plausibility linking cancer risk and long-term calcitonin use (Wells 2016 **Level I**, 22 RCTs, n= 11,489).

The FDA has decided to continue the registration of salmon calcitonin, including for chronic use (FDA 2014b).

4.10.2 | Bisphosphonates

IV pamidronate 30 mg daily (for 3 d) vs placebo, rapidly reduced pain associated with acute osteoporotic vertebral compression fractures (<21 d after incident) for up to 30 d post treatment (Armingeat 2006 **Level II**, n=35, JS 5). Pamidronate IV was as effective as IV human synthetic calcitonin for this indication (Laroche 2006 **Level II**, n=27, JS 3).

Bisphosphonates reduce subacute and chronic bone pain associated with metastatic carcinoma of the breast (Wong 2012 **Level I** [Cochrane], 9 RCTs, n=2,810). In multiple myeloma, there is high quality evidence for benefit in reduction of vertebral fractures and skeletal related events, and low-quality evidence for pain reduction (Mhaskar 2017 **Level I** [Cochrane], 24 RCTs, n=7,293). In advanced prostate cancer, there is no clear benefit to the use of bisphosphonates for reducing pain, but they may prevent further skeletal related events (Macherey 2017 **Level I** [Cochrane], 18 RCTs, n=4,843). Bisphosphonates improve pain control in patients with metastatic bone disease from lung cancer (Lopez-Olivo 2012 **Level I**, 12 RCTs, n=1,767). Zoledronate specifically reduces the likelihood of experiencing a bone pain event in metastatic bone disease in comparison to placebo (RR 0.83; 95%CI 0.76 to 0.89) (Zhu 2013 **Level I**, 12 RCTs, n=4,450). See also Section 8.9.7.7.

There is poor quality evidence for the use of bisphosphonates outside of the aforementioned cancer states (breast, multiple myeloma, prostate, lung), nor is it warranted in patients with short life expectancy (<3 mth) (Porta-Sales 2017 **Level I**, 40 RCTs, n = 16,105).

Bisphosphonates reduce pain in patients with CRPS Type 1, in particular in the early phases of the syndrome (<12 mth) (Chevreau 2017 **Level I**, 4 RCTs, n=181).

In Paget's disease, bisphosphonate use tripled the proportion (31% vs 9%) of participants whose bone pain disappeared (RR 3.42; 95%CI 1.31 to 8.90) (NNT 5) (2 RCTs, n=205) (Corral-Gudino 2017 **Level I** [Cochrane], 20 RCTs [pain], n=3,168). The evidence was limited regarding benefit of specific bisphosphonates, but zoledronate appeared to have marginally better efficacy vs pamidronate and risedronate (2 RCTs, n=436).

In acute pain due to osteoarthritis of the knee, bisphosphonates have no effect on pain, function or radiological progress (Vaysbrot 2018 **Level I**, 7 RCTs, n=3,013).

KEY MESSAGES

1. Bisphosphonates reduce bone pain associated with metastatic breast cancer (**U**), multiple myeloma (**S**) and Paget's disease (**N**) (**Level I** [Cochrane Review]), but have no beneficial effect for knee arthritis (**N**) (**Level I**).
2. Salmon calcitonin reduces pain and improves mobilisation in the acute phase after osteoporosis-related vertebral compression fractures (**U**) (**Level I** [PRISMA]).
3. Bisphosphonates reduce pain in patients with CRPS Type 1 in the early phase of the disease (**N)** (**Level I**).
4. Salmon calcitonin reduces acute, but not chronic, phantom limb pain (**U**) (**Level II**).
5. Pamidronate reduces pain associated with acute osteoporotic vertebral compression fractures (**U**) (**Level II**).

4.11 | Cannabis, cannabinoids and cannabimimetics

4.11.1 | Pharmacology

Medicinal preparations made from the cannabis plant contain several hundred chemical substances, which occur in varying concentrations in different plant strains and growth environments. Cannabis plants and their extracts are uniquely rich in phytocannabinoids (Russo 2011 **NR**), of which delta^9-tetrahydrocannabinol (Δ^9-THC) is the best characterised substance and induces most of the psychogenic effects attributed to cannabis. Tetrahydrocannabinolic acid is the nonpsychotropic phytochemical precursor of THC and is of therapeutic interest for the prevention of nausea (Rock 2013 **BS**) and the selective inhibition of COX-2 (Takeda 2008 **BS**). Other prominent THC congeners include cannabidiol and cannabinol. Cannabidiol (CBD) is of interest because it opposes the psychotropic activity of THC and is currently being developed for anticonvulsant therapy (Schubart 2011 **Level IV**, n=1,877; Devinsky 2014 **NR**; Borgelt 2013 **NR**). Cannabinol is also of interest for possible antitumour actions (Guindon 2011 **NR**).

"Cannabinoids" refers to both the phytocannabinoid congeners of Δ^9-THC and to a wide range of synthetic substances that act on a family of G-protein coupled receptors, which are presently designated subtypes CB_1 and CB_2. CB_1 receptors are predominantly distributed throughout the central and peripheral nervous system, where they mediate inhibition of neurochemical transmitter release and are associated with analgesic and mood modifying effects. CB_2 receptors predominantly occur on immune cells, including microglia, and are associated with modulation of cytokine release and have an anti-inflammatory effect (Mackie 2006 **NR**).

The endogenous cannabinoid system can be considered complementary to the endogenous opioid system (Wilson-Poe 2013 **BS**). Endogenous cannabinoid ligands (endocannabinoids) are derived from arachidonic acid. It is postulated that some (chemically noncannabinoid) analgesic agents (including paracetamol and various NSAIDs) may act, at least in part, via cannabinoid receptor mediation, either directly or indirectly via modulation of endocannabinoid metabolism (Graham 2013a **NR**; Manzanares 2006 **NR**) although much of this evidence is from pre-clinical data and some effects may be species-specific (McPartland 2014 **BS SR**).

It is difficult to group together cannabis-derived preparations and other cannabinoids. This is because plant-extract formulations comprise a mixture of active ingredients (eg the oral mucosal metered-dose spray nabiximols [Sativex®; containing THC:CBD≈1:1] in comparison to pure single ingredient cannabinoid preparations, such as dronabinol [Marinol®, synthetic THC, oral capsules] and nabilone [Cesamet®, synthetic analogue of THC, oral capsules]). Nabiximols are registered in Australia and New Zealand among other countries for treatment of spasticity associated with multiple sclerosis (MS).

The acute toxicity of phytocannabinoids is extremely low; nevertheless, clinical studies of the effect-adverse effect profile of cannabis and cannabinoids have demonstrated that desirable actions may be limited in a proportion of patients due to adverse effects, including dysphoria, sedation and impaired psychomotor performance, memory and concentration (Robson 2011 **NR**).

Many patients self-administer cannabis by smoking; the traditional route popularised by nonmedical users (Wilsey 2013 **Level II**, n=39, JS 4; McQuay 2010 **NR**). Transpulmonary administered phytocannabinoids are rapidly and efficiently absorbed; however, newer vaporising delivery techniques are supplanting smoking with its attendant health risks (Zuurman 2008 **Level II**, n=12, JS 4; Eisenberg 2014 **Level IV PK**; Hazekamp 2006 **EH**) including emerging concerns regarding severe pulmonary toxicity and 'vaping' (Schier 2019 **GL**). Oral cannabis and cannabinoid preparations have a poor and highly variable systemic bioavailability (Huestis 2007 **NR**). Likewise, the oromucosal spray (of nabiximols) does not achieve a rapid systemic absorption, with a profile

resembling oral administration (Karschner 2011a **Level II PK**, n=9, JS 3; Karschner 2011b **Level II EH**, n=22, JS 3; Zuurman 2008 **Level II EH**, n=12, JS 4; Hazekamp 2006 **EH**).

4.11.2 | Efficacy

4.11.2.1 | Acute Pain

A volunteer study considering acute pain used electrical and heat stimuli in healthy young adult female volunteers found 20 mg oral standardised cannabis extract to be no different to 5 mg oral diazepam (active placebo) in a variety of endpoint measures (Kraft 2008 **Level II EH**, n=18, JS 4). The authors concluded that "*cannabinoids are not effective analgesics for the treatment of acute nociceptive pain in humans*". The authors determined the plasma concentrations of the Δ^9-THC and CBD components and found that they varied more than seven-fold between subjects.

Similarly, in the clinical setting, there is no evidence for a role of synthetic or purified cannabinoids in the management of acute pain (Stevens 2017 **Level I** [PRISMA], 7 RCTs, n=310). Five RCTs found cannabinoids to be equivalent to placebo, one inferior and one superior. There were no synergistic or additive analgesic effects when used in combination with opioids.

4.11.2.2 | Chronic Pain

In a variety of chronic pain conditions, including neuropathic pain, fibromyalgia, arthritis and other mixed groups, the efficacy of all commercially available cannabinoids in all study designs and considering all IMMPACT recommended outcomes were analysed (Stockings 2018 **Level IV SR** [PRISMA], 47 RCTs & 57 studies, n=9,958). Across the RCTs, the pooled event rate for 30% pain reduction is 29.0% for cannabinoids vs 25.9% for placebo (OR 1.46; 95%CI 1.16 to 1.84) ($NNT_{30\%}$ 24; 95%CI 15 to 61) (8 RCTs, n=1,734); this outcome is achieved in 72% of patients (95%CI 66%-78%) in observational studies with no comparison group. Across the RCTs, the benefit is lost for 50% pain reduction with pooled event rate of 18.2% vs 14.4% (OR 1.43; 95%CI 0.97 to 2.11) (5 RCTs, n=753). With regard to other outcomes in RCTs, there were no effects on physical functioning, quality of life, overall emotional functioning or depression or anxiety symptoms, but some low level evidence for reduction in sleep problems (moderate level evidence with nabiximols only) and an improved Global Impression of Change (GIC) (perceived "much" to "very much" improved 18.9% vs 11.8%) (OR 1.62; 95%CI 1.34 to 1.96) (NNT 38; 95%CI 27 to 62) (13 RCTs [4 continuous & 9 dichotomous], n=1,896 [1,595 dichotomous]). There is moderate- to high-grade evidence supporting use of nabiximols to achieve modest reductions in pain as adjuvant therapy in MS-related pain. Adverse events occurred in 81.2% of cannabinoid-treated patients vs 66.2% of placebo-treated patients (OR 2.33; 95%CI 1.88 to 2.89) (NNH 6; 95%CI 5 to 8) (10 RCTs, n=1,959); severe adverse events resulting in study withdrawal occurred in 15.8% vs 4.6% (OR 3.47; 95%CI 2.64 to 4.56) (NNH 40; 95%CI 35 to 49) (19 RCTs, n=3,265).

These findings are largely consistent with a preceding meta-analysis with significant overlap of included RCTs (Aviram 2017 **Level I** [PRISMA], 43 RCTs, n=2,437) and an overview of systematic reviews not including the above meta-analyses (Hauser 2018 **Level I** [PRISMA], 10 SRs, unspecified number of RCTs).

In addition to these meta-analyses of effects on all chronic pain conditions, there are also assessments of specific conditions published (with significant overlap of included RCTs):

- In neuropathic pain, there is no high-quality evidence for the efficacy of any cannabis-based medicine (Mucke 2018a **Level I** [Cochrane], 16 RCTs, n=1,750). Low quality evidence shows a 50% or greater pain reduction versus placebo in 21% vs 17% (RD 0.05; 95%CI 0.00 to 0.09) ($NNT_{50\%}$ 20; 95%CI 11 to 100) (8 RCTs, n=1,001). Moderate quality evidence shows a 30% or greater pain reduction in 39 vs 33% (RD 0.09; 95%CI 0.03 to 0.15)

($NNT_{30\%}$ 11; 95%CI 7 to 33) (10 RCTs, n=1,586). For adverse events, evidence is of low quality and shows an increase in nervous system adverse events 61% versus 29% (RD 0.38; 95%CI 0.18 to 0.58) (NNH 3; 95%CI 2 to 6) (9 RCTs, n=1,304) and psychiatric disorders 17% vs 5% (RD 0.10; 95%CI 0.06 to 0.15) (NNH 10; 95% CI 7 to 16) (9 RCTs, n=1,314);

- In fibromyalgia, there is no convincing evidence that nabilone (the only cannabinoid in both RCTs) is of any value in treating this condition (Walitt 2016 **Level I** [Cochrane], 2 RCTs, n=72);
- In cancer pain, very low-quality evidence shows no benefit of nabiximols or THC (the only cannabinoids in the included RCTs) on any outcome including pain, sleep problems and opioid consumption with increased adverse events (GI and nervous system) (Hauser 2019 **Level I** [PRISMA], 5 RCTs, n=1,534). Even for improvement of anorexia or cachexia in a palliative care setting, there is no convincing, unbiased, high quality evidence for an effect of cannabinoids (Mucke 2018b **Level I** [PRISMA], 9 RCTs, n=1,561);
- In MS, cannabinoids may have modest effects for pain or spasticity based on high quality evidence (Nielsen 2018 **Level III-3 SR** [PRISMA], 11 SRs based on 32 studies).

Smoking cannabis has only short-term effects in RCTs of painful HIV associated sensory neuropathy (Phillips 2010 **Level I** [PRISMA], 14 RCTs n=1,764 [2 smoked cannabis, n=111]). Specific to smoked cannabis, the authors caution re potential bias due to difficulties in patient blinding; in one RCT 92% guessed treatment allocation correctly.

A 4 y prospective cohort study of people with chronic non-cancer pain taking opioids identified that those using non-prescribed cannabis had increased pain severity, pain interference and generalised anxiety disorder scores and decreased pain self-efficacy scores (Campbell 2018 **Level III-2**, n=1,514). Cannabis use did not have an opioid-sparing or opioid cessation effect.

4.11.3 | Adverse effects

Transient adverse effects of cannabis and cannabinoids are variable and include impaired cognition, dizziness and sedation. In short-term exposure (mean treatment duration of 2 wk) medical cannabis was not associated with a higher incidence of serious adverse effects vs control (RR 1.04; 95%CI 0.78 to 1.39), with dizziness being reported as the most commonly reported nonserious event in cannabinoid-treated patients (15.5%) (Wang 2008a **Level I**, 23 RCTs, n=3,141).

Longer-term studies in patients with MS have indicated no new safety concerns after several years of administration. Nabiximols (Sativex®) treatment in patients with MS was not associated with psychopathology or impaired cognition (Aragona 2009 **Level II**, n=17, JS 5). Similarly, its adverse effects were assessed in an open-label study following a trial for treating spasticity in MS patients for a mean duration of 334 d (Serpell 2013 **Level IV**, n=146). Adverse effects typically reported as "dizziness", "fatigue" and "headache" caused treatment withdrawal in 14% of patients and were serious (eg psychosis) in 4.3%. A further 9% of these patients withdrew due to lack of efficacy.

There is widespread concern about chronic exposure to cannabis and the development of psychosis in susceptible individuals. Whilst a causal link is yet to be established, one meta-analysis concluded that there is a dose-response relationship between the level of cannabis use and the risk for psychosis (Marconi 2016 **Level III-3** [PRISMA], 10 studies, n=66,816). The risk for schizophrenia and other psychosis-related symptoms is highest in the heaviest cannabis users vs non-users (OR 3.90; 95%CI 2.84 to 5.34). Others have argued that there is little evidence that, at a population level, cannabis use is a primary contributing factor in the development of psychiatric illness (Hamilton 2014 **Level III-3**; Gage 2013 **NR**; Macleod 2010 **NR**).

Rapidly absorbed cannabis (eg by smoking) produces a tachycardia by a beta-adrenergic mechanism (Beaconsfield 1972 **NR**). A detailed literature review identifies an increased risk of acute coronary syndrome and chronic cardiovascular disease associated with cannabis use through other mechanisms postulated as vascular inflammation, platelet activation and carboxyhaemoglobin formation (Richards 2019 **Level IV SR** [PRISMA], 85 studies, n=541,518). However, in patients surviving acute myocardial infarction there was no association between cannabis use and mortality (Frost 2013 **Level IV**, n=519). There are emerging concerns regarding severe pulmonary toxicity related to "vaping", with unclear trigger factors but many reports involve cannabinoids (Schier 2019 **GL**). Overall, cardiovascular and pulmonary effects of cannabinoids need to be considered (Pacher 2018 **NR**).

Acute cannabis intake impairs driving, but the increase in accident risk is of low to medium magnitude (increase in accident risk pooled OR 1.28; 95%CI 1.16 to 1.40 and in culpable accident risk pooled OR 1.42; 95%CI 1.11 to 1.75) (Rogeberg 2019 **Level III-3 SR**, 13 studies [culpability], n=78,023).

After trauma, marijuana use, in particular chronic use, leads to higher pain scores and higher opioid requirements (Salottolo 2018 **Level III-2**, n=261).

Epidemiological evidence of harms is typically derived from "recreational" users where the "cannabis" is defined neither chemically nor posologically (dose) and its relevance to the medical use, particularly of pharmaceutical grade cannabis, in supervised patients, is questionable.

4.11.4 | General considerations

It should be noted that all clinical studies to date have various design limitations, most involving small numbers of patients and most using only nonselective highly lipophilic cannabinoids, often of unknown composition. It should also be noted that several RCTs with negative results are yet to be published. The possible benefits from more selective agonists have yet to be investigated in the clinical setting, along with more innovative or reliable modes of administration.

Many leading stakeholder institutions world-wide, which hold either scientific, best practice or regulatory interests in the use of pharmacological agents for the treatment of pain, express a universal concern for the proliferation of cannabis related products for the indications of acute or chronic pain (FPMANZCA 2019b **GL**). This concern is largely underpinned by the current lack of quality and robust evidence for its efficacy and the significant adverse effects both in the short and long terms. These same institutions welcome further dialogue within the framework of well-designed clinical studies to better determine usefulness of cannabinoids and their side-effect profile.

KEY MESSAGES

1. Adverse effects including dizziness, cognitive changes and psychiatric symptoms (eg psychosis) may limit the usefulness of cannabinoids in pain treatment (**S**) (**Level I** [Cochrane Review]).
2. Current evidence does not support the use of cannabinoids in acute pain management (**S**) (**Level I** [PRISMA]).
3. Smoking cannabis has short-term efficacy in neuropathic pain in patients with HIV/AIDS, although potential study bias means that this is not recommended as routine treatment (**Q**) (**Level I** [PRISMA]).
4. Cannabinoids appear to be mildly effective when used in the treatment of pain and spasticity associated with multiple sclerosis and HIV (**W**) (**Level III-2 SR** [PRISMA]).
5. Smoked cannabis increases the risk of acute coronary syndrome and chronic cardiovascular disease (**N**) (**Level IV SR**).

4.12 | Corticosteroids

4.12.1 | Systemic corticosteroids

Surgical tissue trauma leads to the conversion of arachidonic acid to prostaglandins and leukotrienes. NSAIDs inhibit the formation of prostaglandins, whereas corticosteroids also inhibit the production of leukotrienes and cytokines (Royse 2017 **NR**; Gilron 2004 **NR**). The anti-inflammatory effects of corticosteroids account for some, but not all, of the antinociceptive effects of corticosteroids seen in clinical practice. It is likely that the analgesic actions of systemically administered corticosteroids are attributable predominantly to rapid-onset nongenomic mechanisms. However, the well-documented anti-inflammatory actions may contribute to a more delayed analgesic effect and may be due to genomic effects (Rijsdijk 2014 **NR**; Lowenberg 2008 **NR**). See also paediatric Section 10.4.10.

4.12.1.1 | Efficacy

Perioperative administration of corticosteroids reduces the severity of postoperative pain and decreases analgesic requirements as discussed below. However, corticosteroids are not only administered in the perioperative setting for their analgesic effects but also for other reasons. These include (but are not limited to) a reduction of PONV (De Oliveira 2013b **Level I** [PRISMA], 60 RCTs, n=6,696), decreased swelling in dental and maxillofacial surgery (Dan 2010 **Level I**, 12 RCTs, n=574) and an improvement in quality of recovery and decreased postoperative fatigue (Yue 2017 **Level I**, 11 RCTs, n=774; Murphy 2014 **Level II**, n=200, JS 5; Murphy 2011a **Level II**, n=120, JS 5; Murphy 2011b **Level II**, n=117, JS 5) with facilitation of earlier hospital discharge (Murphy 2011a **Level II**, n=120, JS 5).

Corticosteroids have also been shown to have antihyperalgesic effects in animals and humans (Romundstad 2007 **NR**; Brandsborg 2007 **NR**). In experimental burn injury pain, both methylprednisolone and ketorolac reduced secondary hyperalgesia and increased pain pressure tolerance threshold vs placebo, although the increase in pain pressure tolerance threshold was greater with ketorolac (Romundstad 2007 **Level II EH**, n=12, JS 4). In surgical patients, preoperative administration of methylprednisolone resulted in significantly less hyperalgesia vs parecoxib and placebo but there was no reduction in persistent spontaneous or evoked pain (Romundstad 2006 **Level II**, n=204, JS 4).

Dexamethasone 1.25–20 mg administration to surgical patients decreases postoperative pain scores, opioid consumption, time to first analgesia, requirements for rescue analgesia and PACU LOS (Waldron 2013 **Level I** [PRISMA], 45 RCTs, n=5,796). However, the differences are small and, while statistically significant, unlikely to confer clinically relevant analgesic benefit (eg 13% reduction in postoperative opioid consumption equals 3 mg morphine equivalent over the first 24 h). Preoperative dexamethasone administration is superior to later administration. When steroid doses were classified into three levels, an optimal dose of 0.1 to 0.2 mg/kg dexamethasone was identified (De Oliveira 2011 **Level I** [PRISMA], 24 RCTs, n=2,751); however, a subsequent metaregression did not identify any dose-response relationship for an opioid-sparing effect (Waldron 2013 **Level I** [PRISMA], 45 RCTs, n=5,796).

Systemic dexamethasone 4–40 mg improves quality of analgesia after spinal anaesthesia, with reduced 24 h morphine consumption (6 RCTs, n=326) and prolonged time to first analgesia request (Heesen 2019 **Level I** [PRISMA], 17 RCTs, n=1,133). Systemic 0.5 mg/kg and caudal dexamethasone 0.1–0.2 mg/kg doubles to triples the duration of analgesia from caudal blockade after paediatric surgery to a similar extent (Chong 2018 **Level I** [PRISMA], 14 RCTs, n=1,315).

Orthopaedic surgery

After THA and TKA, glucocorticoids in a dose greater than 0.1 mg/kg dexamethasone equivalent seem to be required to achieve reduction of PONV and pain severity within the first 24 h only (Yue 2017 **Level I**, 11 RCTs, n=774); in addition, systemic steroids are associated with faster functional rehabilitation and greater inflammation control. This is supported by another parallel meta-analysis of elective primary THA with perioperative glucocorticoid administration (dexamethasone 8 to 40 mg, methylprednisolone 125 mg or hydrocortisone 200 mg) (Li 2017c **Level I**, 6 RCTs, n=449).

In patients undergoing elective TKA, perioperative dexamethasone 5–10 mg administration decreases postoperative pain scores at 12, 24, and 48 h, and decreases opioid consumption up to 12 h only vs placebo or control (Zhou 2018 **Level I**, 6 RCTs, n=576). Similar effects are achieved with dexamethasone 10–40 mg in THA (Fan 2018 **Level I** [PRISMA] 3 RCTs, n=207).

High-dose methylprednisolone (dexamethasone equivalent >10 mg), but not low-dose systemic perioperative corticosteroid administration improves analgesia in patients undergoing elective knee or hip surgery (Lunn 2013 **Level I** [PRISMA], 17 RCTs [15 vs placebo], n=1,081). After orthopaedic surgery, there was no difference in the analgesic effect of IV methylprednisolone 125 mg vs IV ketorolac 30 mg, with both being better than placebo; IV methylprednisolone led to greater opioid-sparing but there was no difference in the incidence of adverse effects (Romundstad 2004 **Level II**, n=75, JS 5).

Tonsillectomy

Dexamethasone in doses >10 mg over 24 h given to adults undergoing tonsillectomy appears to decrease postoperative pain, an effect further improved by repeated administration in the postoperative period (Diakos 2011 **Level I**, 7 RCTs, n=580). This has been confirmed by a subsequent meta-analysis, which shows pain reduction by 23% at 4 h (MD -1.4/10; 95% CI -1.6 to -1.2) (Tolska 2019 **Level I** [PRISMA], 10 RCTs [dexamethasone], n=590) (6 RCTs overlap).

In a mixed meta-analysis of tonsillectomy in adults and children, all steroids reduce pain severity at all time points up to 7 d with a peak benefit on POD 1 (SMD -0.99/10; 95%CI -1.32 to -0.67) (41 RCTs, n=3,477) (Titirungruang 2019 **Level I** [PRISMA], 64 RCTs, n=6,327) (8 RCTs overlap with Tolska 2019). These effects are similar for systemic vs local steroid administration. Furthermore, steroids reduce PONV (OR 0.31; 95%CI 0.24 to 0.40) (46 RCTs, n=4,784), while not increasing the risk of primary (OR 0.96; 95%CI 0.55 to 1.67) (15 RCTs, n=1,736) or secondary haemorrhage (OR 1.05; 95%CI 0.74 to 1.51) (23 RCTs, n=2,440).

Thyroidectomy

Dexamethasone in adults undergoing thyroidectomy reduces postoperative pain scores and analgesic requirements vs control (Chen 2012 **Level I** [PRISMA], 5 RCTs, n=497) and the need for rescue analgesia vs placebo (Zou 2014 **Level I**, 13 RCTs, n=2,180). Only higher dose dexamethasone (8 to 10 mg) appeared to confer this analgesic benefit.

Maxillofacial surgery

Similarly, after maxillofacial surgery, the perioperative administration of corticosteroids (dexamethasone equivalent >5 mg) results in significant analgesic effects vs placebo in addition to decreased swelling (Dan 2010 **Level I**, 12 RCTs, n=574).

In rhinoplasty surgery, dexamethasone/pregabalin showed significant analgesic benefits up to 24 h vs placebo/pregabalin vs placebo/placebo (Demirhan 2013 **Level II**, n=60, JS 3).

Other surgery

In lumbar disc surgery, PO dexamethasone 16 mg preoperatively reduced pain with mobilisation in the first 24 h postoperatively vs placebo (Nielsen 2015b **Level II**, n=160, JS 5).

After mixed ambulatory surgery, ketorolac provided better pain relief than either dexamethasone or betamethasone in the immediate postoperative period but there were no differences in pain relief or analgesic use in the 4 to 72 h period after surgery (Thagaard 2007 **Level II**, n=179, JS 5).

A combination of dexamethasone/gabapentin provided better pain relief and led to less PONV than either medicine given alone after varicocoele surgery; both the combination and the individual medicines were more effective than placebo (Koç 2007 **Level II**, n=80, JS 5). In contrast, there was no difference in pain scores or PCA-morphine requirements during the first 24 h postoperatively in patients given pregabalin, dexamethasone/pregabalin or placebo after hysterectomy (Mathiesen 2009 **Level II**, n=116, JS 5).

Nonetheless, not all of the procedure-specific trials demonstrate benefit. Dexamethasone 0.1 mg/kg did not decrease the severity of pain nor opioid consumption up to 72 h in patients undergoing thoracotomy vs placebo (Joung 2018 **Level II**, n=40, JS 4). Likewise, in patients undergoing elective bowel surgery, dexamethasone 8 mg did not improve the quality of recovery, fatigue nor pain severity at 120 h postoperatively vs control (Dreams Trial Collaborators 2017 **Level II**, n=1,350, JS 5). When added to a multimodal analgesic combination including intrathecal morphine for Caesarean section under spinal anaesthesia, dexamethasone 8 mg did not decrease opioid consumption up to 24 h postoperatively (Ituk 2018 **Level II**, n=52, JS 4).

After breast augmentation, IV methylprednisolone 125 mg and IV parecoxib 40 mg provided comparable analgesia; however, PONV and fatigue scores were lower in the patients given methylprednisolone (Romundstad 2006 **Level II**, n=204, JS 4). In cardiac surgery, IV methylprednisolone 250 mg at induction and repeated immediately prior to cardiopulmonary bypass did not reduce the incidence of delirium nor improve the quality of recovery vs placebo (Royse 2017 **Level II**, n=555, JS 5). Oral prednisolone 50 mg preoperatively did not improve pain, fatigue, nausea or vomiting in patients undergoing laparoscopic cholecystectomy vs placebo (Bisgaard 2008 **Level II**, n=200, JS 3). In total abdominal hysterectomy, methylprednisolone 125mg did not confer analgesic benefit vs placebo (Aabakke 2014 **Level II**, n=49, JS 4).

Sore throat

Corticosteroids administered in a single dose (most commonly PO dexamethasone 10 mg) provide pain relief for sore throat including pharyngitis more effectively and faster than placebo (8 RCTs, n=907) (Sadeghirad 2017 **Level I**, 10 RCTs, n=1,426).

Dexamethasone 0.1–0.2 mg/kg decreases incidence (9 RCTs, n=983) and severity (4 RCTs, n=431) of sore throat after extubation when administered IV at induction vs placebo (Kuriyama 2019 **Level I**, 15 RCTs, n=1,849).

Acute gout

In acute gout, corticosteroids provide similar analgesic effects to non-corticosteroid treatments (Liu 2017b **Level I** [PRISMA], 7 RCTs, n=929).

4.12.1.2 | Adverse effects

The principal safety concerns of perioperative corticosteroid administration relate to the development of hyperglycaemia, increased infection and bleeding risk and the risk of recurrence of malignancy (Ali Khan 2013 **NR**; Yee 2013a **NR**; Turan 2011 **NR**; Ho 2011 **NR**).

Two meta-analyses have examined these safety issues with similar conclusions, although with significant methodological differences and including all corticosteroids (Toner 2017 **Level I**,

11 RCTs [hyperglycaemia], n=685; Polderman 2018 **Level I** [Cochrane], 38 RCTs, n=4,931) (17 RCTs overlap). However, the RCTs summarised in these meta-analyses are essentially efficacy studies of the antiemetic and anti-inflammatory effects of dexamethasone. Few trials have examined long-term effects or patient outcomes and those that have, were not adequately powered to do so. In consequence, a large RCT (PADDI) has completed recruitment, the results of which will address many of the safety issues relating to the administration of intraoperative dexamethasone (Corcoran 2019 **Trial Protocol**, n=8,880).

Hyperglycaemia

In non-cardiac surgical patients, glucocorticoids increase blood glucose concentrations (WMD 1.1 mmol/L; 95%CI 0.6 to 1.6) up to 12 h postoperatively (Toner 2017 **Level I**, 11 RCTs [hyperglycaemia], n=685). When only trials which excluded patients with diabetes were examined, the observed increase in blood glucose is smaller (WMD 0.7 mmol/L). These findings are confirmed by the subsequent meta-analysis of dexamethasone only, which finds a similar increase in non-diabetic patients (10 RCTs, n=595) and a more pronounced increase (1.8 mmol/L) in diabetic patients (2 RCTs, n=74) (Polderman 2018 **Level I** [Cochrane], 38 RCTs, n=4,931).

A large dose of dexamethasone (1 mg/kg at induction) in cardiac surgery patients, not excluding diabetic patients, resulted in a higher maximum postoperative blood-glucose concentration (MD 0.9 mmol/L) vs placebo (Dieleman 2012 **Level II**, n=4,494, JS 5). As all patients received glucose-lowering therapy in the ICU postoperatively, the dexamethasone effect may have been mitigated.

Infection risk

The administration of dexamethasone to patients undergoing surgery is not associated with an increase in the risk of any infection (OR 1.01; 95%CI 0.80 to 1.27) (Polderman 2018 **Level I** [Cochrane] (27 RCTs [infection], n=4,931]). This is also shown for all corticosteroids (OR 0.9; 95%CI, 0.6 to 1.3) (Toner 2017 (**Level I** [PRISMA], 18 RCTs [infection], n=2,138). There is also no increase in impaired wound healing or anastomotic leakage.

In cardiac surgery, a single intraoperative high dose of dexamethasone (1 mg/kg) did not significantly increase the incidence of postoperative wound infection; there was actually a reduction in total infection complications, due mainly to a reduction in pneumonia (Dieleman 2012 **Level II**, n=4,494, JS 5).

Bleeding risk

Perioperative corticosteroids do not increase the risk of postoperative haemorrhage in non-cardiac surgery (OR, 1.4; CI, 0.7 to 2.7) (Toner 2017 (**Level I** [PRISMA], 18 RCTs [bleeding], n=2,138).

Specifically, in paediatric tonsillectomy dexamethasone does not increase the overall bleeding risk; however, its use increases the need for operative intervention for bleeding (Plante 2012 **Level I**, 29 RCTs, n=2,674).

See paediatric section 10.4.10.3 for details of corticosteroid effects on bleeding risk.

Malignancy recurrence

There are limited and contradictory results on recurrence of malignancy; after colorectal surgery there was an increase in one small RCT (Singh 2014 **Level II**, n=43, JS 4), while a propensity-matched study failed to confirm such an association following ovarian cancer surgery (De Oliveira 2014b **Level III-2**, n=260).

KEY MESSAGES

1. Mild increase in blood glucose concentration follows perioperative administration of dexamethasone (**S**) (**Level I** [Cochrane Review]) and all corticosteroids (**S**) (**Level I** [PRISMA), particularly in patients with diabetes mellitus.
2. Perioperative administration of dexamethasone (**N**) (**Level I** [Cochrane Review]) and all corticosteroids (**N**) (**Level I** [PRISMA]) does not increase the risk of infection.
3. Perioperative administration of dexamethasone reduces postoperative pain and opioid requirements to a limited extent but also reduces nausea and vomiting, fatigue, and improves the quality of recovery compared with placebo (**U**) (**Level I** [PRISMA]).
4. Preoperative dexamethasone appears to be more effective than intraoperative or postoperative administration (**U**) (**Level I** [PRISMA]).
5. Perioperative corticosteroids do not increase the risk of impaired wound healing, anastomotic leakage or postoperative haemorrhage (**N**) (**Level I** [PRISMA]).
6. A single dose of corticosteroids provides more effective and faster relief of pain from sore throat than placebo (**N**) (**Level I**) and decreases incidence and severity of sore throat after extubation when administered at induction (**N**) (**Level I** [PRISMA]).
7. Systemic dexamethasone reduces pain intensity and opioid requirements after spinal anaesthesia (**N**) (**Level I** [PRISMA].

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ As all adverse event data on corticosteroid use in surgical populations are based to date on efficacy trials (with methodological differences), their long-term safety awaits further evaluation (**N**).

4.12.2 | Regional corticosteroids

4.12.2.1 | Neuraxial

Caudal 0.1 to 0.2 mg/kg and IV dexamethasone (mostly 0.5 mg/kg) doubles to triples the duration of analgesia from caudal blockade after paediatric surgery to a similar extent (Chong 2018 **Level I** [PRISMA], 14 RCTs, n=1,315).

Dexamethasone when added to bupivacaine/fentanyl solution in epidural analgesia prolonged duration of analgesia in abdominal or thoracic surgery (372 min ± 58.1 vs 234.6 min ± 24.3) and decreased opioid requirements in the first 24 h (Naghipour 2013 **Level II**, n=72, JS 5). In patients having lower abdominal surgery, single-dose epidural bupivacaine/dexamethasone had similar prolongation of time to first analgesia, opioid-sparing and antiemetic effects as bupivacaine/fentanyl when compared with epidural bupivacaine alone (Khafagy 2010 **Level II**, n=90, JS 5). Preoperative single-dose epidural administration of dexamethasone, with or without bupivacaine, reduced postoperative pain and morphine consumption following laparoscopic cholecystectomy (Thomas 2006 **Level II**, n=94, JS 5). Epidural dexamethasone/ropivacaine reduced postoperative pain in patients undergoing gastrectomy under epidural analgesia vs ropivacaine alone in a dose-dependent way with 10 mg superior to 5 mg (Hong 2017 **Level II**, n=120, JS 5). Use

of epidural methylprednisolone resulted in no difference in morphine requirements or pain scores following thoracotomy vs epidural saline (Blanloeil 2001 **Level II**, n=24, JS 4).

Epidural corticosteroids (triamcinolone, methylprednisolone or dexamethasone) applied by the surgeons intraoperatively for microdiscectomy or laminectomy reduce pain at 24 h and 1 mth postoperatively, as well as opioid requirements and hospital LOS vs placebo (Wilson-Smith 2018 **Level I** [PRISMA], 17 RCTs, n=1,727; Arirachakaran 2018 **Level I** [PRISMA], 12 RCTs, n=1,006) (10 RCTs overlap). There is no difference in complications; a meta-analysis looking specifically for complications found no significant difference in overall complications (RR 1.94; 95%CI 0.72 to 5.26) nor infectious complications (RR 4.58; 95%CI 0.75 to 27.95) (Akinduro 2015 **Level III-2 SR**, 16 RCTs & 1 study, n=1,933).

Lumbar epidural steroid injections (ESI) for acute sciatica provide small but significant short-term relief (≤3 mth) from acute radicular pain (MD -6.2/100; 95%CI -3.0 to -9.4) and reduce disability but do not provide significant longer-term benefits beyond this time (Pinto 2012 **Level I,** 23 RCTs, n=2,334). Results specifically for transforaminal ESI vs saline or local anaesthetic are similar, with modest but significant pain reduction at 3 mth (MD−0.97/10; 95% CI −1.42 to −0.51) but no benefit on disability or need for later surgery (Bhatia 2016 **Level I** [PRISMA] 8 RCTs, n=771) (4 RCTs overlap).

Several meta-analyses overlapping for multiple studies with each other and the above have analysed specific questions. ESI is superior to saline (6 RCTs) with regard to improved function and pain control and superior to local anaesthetic with regard to improved pain control (2 RCTs), but these findings are only maintained at 1 mth with no significant long-term advantage (Lee 2018a **Level I**, 14 RCTS, n=1,502). Fluoroscopically guided lumbar ESI provide significant short-term improvement of radicular pain caused by lumbar disc herniation and stenosis, but not for axial back pain, based on low-quality evidence (Sharma 2017 **Level IV SR**, 41 studies, n unspecified). Non-image guided ESI provides inferior short-term improvement based on low-quality evidence and should only be performed if image-guidance is not available (Vorobeychik 2016 **Level IV SR**, 39 studies, n unspecified). Transforaminal ESI compared to interlaminar ones result in better short-term pain control (2 to 4 wk) based on weak evidence with no other significant benefits (Lee 2018c **Level III-2 SR**, 10 RCTs & 2 studies, n=876). There is no significant difference between transforaminal and caudal ESI based on very weak evidence (Lee 2018b **Level III-2 SR**, 4 RCTs & 2 studies, n=567). Preganglionic (supraneural, retrodiscal) ESI increases the chance of effectiveness vs postganglionic injection (Pairuchvej 2018 **Level III-2 SR**, 3 RCTs & 1 study, n=412). Particulate steroids compared to non-particulate ones result in statistically significant, but clinically questionable improved pain control (MD -0.53/10; 95%CI -0.14 to -0.92) (Makkar 2016 **Level III-2 SR**, 4 RCTs & 3 studies, n=4,398). For fluoroscopically guided cervical transforaminal epidural steroid injections, the response rate for <50% pain reduction is 48% (95%CI 34 to 61%) at 1 mth (5 studies, n=164) and 62% (95%CI 49 to 75%) at 3 mth (4 studies, n=259), based on very low-quality studies with no control group comparison (Conger 2020 **Level IV SR** [PRISMA], 17 studies, n unspecified).

The FDA issued a warning in April 2014 that injection of corticosteroids into the epidural space of the spine may result in rare but serious adverse effects, including loss of vision, stroke, paralysis and death (FDA 2014a **GL**). These concerns have been subsequently addressed in a number of consensus statements by multiple organisations (Rathmell 2015 **GL**; Kennedy 2015 **GL**). Recommendations particularly address image-guidance and use of particulate vs non-particulate steroids and have led to subsequent discussions in the literature.

Furthermore, repeat ESI (mean 1 to 14.7 injections with cumulative methyl-prednisolone equivalent doses of 80 to 8,130 mg) are associated with reduced bone mineral density and increased risk of vertebral fractures (Kerezoudis 2018 **Level IV SR**, 8 studies, n=7,233).

When compared with local anaesthetic PNB alone, the addition of dexamethasone 4–10mg to local anaesthetic prolongs the duration of sensory block (MD 6.70 h; 95%CI 5.54 to 7.85), and reduces postoperative pain intensity at 12 h (MD -2.08/10; 95%CI -2.63 to -1.53) and 24 h (MD -1.63/10; 95%CI -2.34 to -0.93) (Pehora 2017 **Level I** [Cochrane]**,** 35 RCTs, n=2,702). Another meta-analysis has similar results for analgesia outcomes and also finds a decrease in PONV (RR 0.36; 95%CI 0.19 to 0.70) (Huynh 2015 **Level I** [PRISMA]**,** 12 RCTs, n=1,054) (9 RCTs overlap). Specifically in brachial plexus block, there were similar findings for dexamethasone 1–10 mg, with low quality evidence of a ceiling effect of dexamethasone at 4 mg (Kirkham 2018 **Level I** [PRISMA]**,** 33 RCTs, n=2,138) (23 RCTs overlap with Pehora 2017). The effect on duration of sensory block is more pronounced with bupivacaine (MD 4.0 h; 95%CI 2.8 to 5.2) (4 RCTs, n=429) than with ropivacaine (MD 2.0 h; 95%CI -0.5 to 4.5 h) (5 RCTs, n=357) (Baeriswyl 2017 **Level I** [PRISMA]**,** 11 RCTs, n=914) (10 RCTs overlap with Pehora 2017).

IV dexamethasone vs placebo (8 RCTs, n=499) increases the duration of sensory block (MD 6.21 h; 95%CI 3.53 to 8.88) and reduces postoperative pain intensity at 12 h (MD -1.24/10; 95%CI -2.44 to -0.04) and 24 h (MD -1.26/10; 95% CI -2.23 to -0.29) as well as postoperative opioid consumption to 24 h (MD -6.58 mg; 95% CI -10.56 to -2.60) (Pehora 2017 **Level I** [Cochrane]**,** 35 RCTs, n=2,702).

Perineural vs IV dexamethasone (9 RCTs, n=720) increases the duration of sensory block (MD 3.14 h; 95%CI 1.68 to 4.59), but improves analgesia only in a clinically insignificant way and has no opioid-sparing effect (Pehora 2017 **Level I** [Cochrane]**,** 35 RCTs, n=2,702). However, a subsequent meta-analysis using the Hartung-Knapp-Sidik-Jonkman (HKSJ) methodology, which the authors claim to provide a more conservative estimate of effect, does not confirm the extended duration of sensory block with perineural vs IV dexamethasone 4–10mg (Hussain 2018 **Level I**, 14 RCTs, n=1,007) (9 RCTs overlap).

Adding dexamethasone 4 mg perineurally as an adjuvant to saphenous nerve block increased the duration of analgesia vs placebo (Bjorn 2017 **Level II**, n=40, JS 5). However, time to first rescue analgesia was similar with dexamethasone 4 mg perineurally for an ankle block vs IV 10 mg administration (Marty 2018 **Level II,** n=100, JS 5). Dexamethasone 8 mg/bupivacaine versus IM dexamethasone 8 mg for sciatic and ankle blocks improved pain scores at 24 h in the sciatic group only, but conferred no other analgesic benefits in either group (Fredrickson 2013 **Level II**, n=126, JS 5).

Perineural dexamethasone 4 to 8 mg for TAPB prolongs sensory block duration (MD 2.98 h; 95%CI 2.19 to 3.78) and reduces pain scores at 2, 6 and 12 h postoperatively (Chen 2018b **Level I** [PRISMA] 9 RCTs, n=575). It also reduces systemic analgesic consumption (SMD -1.29; 95%CI -1.88 to -0.70) and PONV incidence (OR 0.28; 95%CI 0.16 to 0.49) on POD 1.

Dexamethasone 8 mg/bupivacaine vs bupivacaine alone for thoracic paravertebral block improved analgesia and duration of analgesia in patients undergoing nephrectomy (Tomar 2017 **Level II**, n=60, JS 4).

Further addition of dexamethasone 8 mg to local anaesthetics for scalp nerve blocks in the setting of perioperative systemic dexamethasone therapy did not prolong duration of the block (Jose 2017 **Level II**, n=90, JS 5).

Although perineural dexamethasone has been shown to prolong sensory and motor block of perineural local anaesthetics, there is little safety data to support its use. Animal data to date are reassuring, with dexamethasone not increasing ropivacaine-induced sensory nerve toxicity at clinically relevant concentrations (Williams 2011 **BS**) and dexamethasone attenuating bupivacaine-induced neuronal injury (Ma 2010 **BS**). In a meta-analysis, although underpowered for complications, there is no difference in complications or nerve injury (10 RCTs, n=763) (Hussain 2018 **Level I**, 14 RCTs, n=1,007). However, given the lack of human safety data, the practice of

perineural dexamethasone administration needs to be further evaluated (Rahangdale 2014 **NR**). Furthermore, mixtures of ropivacaine and nonparticulate dexamethasone sodium phosphate demonstrated a pH-dependent crystallisation and the use of such combinations may be not advisable (Watkins 2015 **BS**).

4.12.2.3 | Peripheral sites

Periarticular injection of combinations of local anaesthetic, opioid and anti-inflammatory agents including steroids have been studied (LIA), however the range of mixtures makes determination of the effect of individual components difficult. In patients having simultaneous bilateral TKAs, bupivacaine/fentanyl/methylprednisolone were infiltrated by the surgeon around one knee but not the other (Mullaji 2010 **Level II**, n=40, JS 4). Pain scores on the infiltrated side were significantly lower and the joint had greater active flexion up to 4 wk and superior quadriceps recovery up to 2 wk after surgery vs the noninfiltrated knee. Periarticular injection of a mixture of bupivacaine/morphine/adrenaline/clonidine showed a reduced hospital LOS by 24 h without any significant effect on pain relief, motion or function following TKA, when methylprednisolone was added (Christensen 2009 **Level II**, n=76, JS 4). In comparing ropivacaine/adrenaline in three groups with no added steroid, triamcinolone 40 mg and 80 mg, the addition of corticosteroid to periarticular injection of local anaesthetic did not improve pain relief or range of movement outcomes for up to 12 wk of follow-up (Chia 2013 **Level II**, n=126, JS 5).

Intra-articular (IA) corticosteroid injections would be expected to have a direct analgesic effect in inflammatory arthropathies. Following knee joint arthroscopy, IA steroids were more effective than placebo in reducing pain, analgesic consumption and duration of immobilisation, either alone (Wang 1998 **Level II**, n=60, JS 4) or in conjunction with opioids (Kizilkaya 2005 **Level II**, n=72, JS 4; Kizilkaya 2004 **Level II**, n=60, JS 2) and/or local anaesthetics (Moeen 2017, **Level II,** n= 60, JS 5; Rasmussen 2002 **Level II**, n=60, JS 3). Dexamethasone on its own was less effective than pethidine or fentanyl (Saryazdi 2006 **Level II**, n=48, JS 3). A single IA injection of methylprednisolone one wk before TKA did not reduce acute postoperative pain (Luna 2017 **Level II,** n=48, JS 4). There may be a higher risk of septic arthritis with IA steroids (Armstrong 1992 **Level IV**, n=4,256).

Subacromial injections of corticosteroids have been shown to be effective in treating rotator cuff tendonitis for up to 9 mth vs placebo (NNT 3.3; 95%CI 1.8 to 7.7) and are superior to oral NSAIDs (NNT 2.5; 95%CI 1 to 9) (Arroll 2005 **Level I** [QUOROM], 7 RCTs, n=347). In patients with tendonitis of the shoulder or elbow, steroid injections show similar benefits to NSAIDs for early (up to 1 wk) pain relief (Gaujoux-Viala 2009 **Level I**, 20 RCTs, n=1,731).

In patients having hand surgery, IVRA using a combination of lidocaine/dexamethasone resulted in lower pain scores and lower analgesic requirements for 24 h vs lidocaine alone or lidocaine IVRA with IV dexamethasone in the nonoperative arm (Bigat 2006 **Level II**, n=75, JS 2). The addition of dexamethasone to lidocaine/ketorolac IVRA for hand surgery improved intraoperative tourniquet tolerance and postoperative analgesia vs lidocaine IVRA alone (Jankovic 2008 **Level II**, n=45, JS 3).

KEY MESSAGES

1. For brachial plexus blocks, addition of dexamethasone to local anaesthetic prolongs the duration of sensory and motor block and improves postoperative analgesia with only very limited benefits over systemic administration (**S**) (**Level I** [Cochrane Review]).
2. For transverse abdominis plane blocks, addition of dexamethasone to local anaesthetics prolongs the duration of sensory block, improves postoperative analgesia and PONV with no comparison to systemic administration (**N**) (**Level I** [PRISMA]).
3. After spinal surgery, epidural steroid application intraoperatively by the surgeon provides analgesic benefit up to 24 hours and reduces length of stay (**N**) (**Level I** [PRISMA]).
4. For acute radicular pain, lumbar epidural corticosteroid administration is effective for short-term relief (**S**) (**Level I** [PRISMA]).
5. Subacromial injections of corticosteroids are superior to oral NSAIDs in treating rotator cuff tendonitis (**U**) (**Level I** [QUOROM]).
6. For peripheral nerve blocks, addition of dexamethasone to local anaesthetics prolongs the duration of sensory block and improves postoperative analgesia with only limited benefits over systemic administration (**N**) (**Level II**).
7. For epidural analgesia, addition of dexamethasone improves postoperative analgesia and reduces opioid requirements (**N**) (**Level II**).
8. Addition of dexamethasone to intravenous regional anaesthesia with lidoocaine improves analgesia for up to 24 hours (**U**) (**Level II**).
9. Addition of corticosteroid to periarticular injection of local anaesthetic does not improve pain relief or range of movement following total knee arthroplasty (**U**) (**Level II**).
10. Following knee joint arthroscopy, intra-articular steroids in combination with either local anaesthetic or opioids reduce pain, analgesic consumption and duration of immobilisation (**U**) (**Level II**).
11. There is a risk of septic arthritis with intra-articular steroids (**U**) (**Level IV**).
12. Repeat epiudural steroid injections are associated with reduced bone mineral density and increased risk of vertebral fractures (**N**) (**Level IV SR).**

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Concerns have been raised regarding the safety of epidural steroids (**U**).

☑ There is little data in humans regarding the neurotoxicity of perineural corticosteroids (**N**).

4.13 | Other regional analgesic medicines

4.13.1 | Midazolam

Preservative-free midazolam has been proposed as a spinal analgesic due to its action on $GABA_A$ receptors. Robust safety data for the use of intrathecal (IT) midazolam in humans is lacking (Yaksh 2017 **NR**), consequently midazolam is currently not licenced for IT use. Several studies in animal models have raised concern about IT midazolam toxicity (Williams 2011 **BS**; Lavand'homme 2006 **NR**; Yaksh 2004 **NR**; Erdine 1999 **BS**; Malinovsky 1991 **NR**). However, cumulative experience with IT midazolam in human trials confirms beneficial analgesic activity with no demonstrable irreversible side effects vs placebo (Ho 2008 **Level I**, 13 RCTs, n=672; Yaksh 2017 **NR**; Staikou 2014 **NR**). There is insufficient long-term data to unequivocally exclude long-term neurological complications, although none have yet been reported.

IT midazolam added to IT local anaesthetic in perioperative and peripartum patients in comparison with IT local anaesthetic alone shows a reduced incidence of nausea and vomiting and delayed time to request for rescue analgesia (WMD 99 min; 95%CI 76 to 121), but did not affect the duration of motor block (Ho 2008 **Level I**, 13 RCTs, n=672). Multiple subsequent RCTs have confirmed these findings as well as earlier onset and better quality of analgesia for addition of IT midazolam to IT local anaesthetics vs IT local anaesthetic alone (Abdollahpour 2015 **Level II**, n=75, JS 4; Selvaraj 2015 **Level II**, n=100, JS 3; Chattopadhyay 2013 **Level II**, n=90, JS 5; Shadangi 2011 **Level II**, n=100, JS 4), compared to addition of IT dexmedetomidine (Shukla 2016 **Level II**, n=80, JS 3; Samantaray 2015 **Level II**, n=60, JS 4) or IT fentanyl (Codero 2016 **Level II**, n=40, JS 3; Safari 2012 **Level II**, n=90, JS 3) and also when added to IT fentanyl (Gupta 2015 **Level II,** 75 patients, JS 4) or IT sufentanil (Salimi 2014 **Level II**, n=80, JS2). In addition, IT midazolam decreased the incidence of transient neurologic symptoms with IT lidocaine (Selvaraj 2015 **Level II**, n=100, JS 3). Overall, an optimum dose of IT midazolam has not been clearly determined; doses less than 1 mg probably have no effect on prolongation of spinal blockade or analgesia, and the commonly effective doses administered in clinical trials range between 1 to 2 mg (Staikou 2014 **NR**). On the basis of the above meta-analyses, reviews and trials, IT midazolam may cause mild, but not excessive sedation, no additional cardio-respiratory adverse effects or urinary retention.

Specific to the obstetric population, IT midazolam does not seem to have any deleterious effect on infants' Apgar scores (Abdollahpour 2015 **Level II**, n=75, JS 4). IT midazolam 1 mg as a part of combined spinal epidural technique in pre-eclamptic parturients undergoing elective Caesarean section is inferior to IT preservative free magnesium sulphate 50 mg with regard to prolongation of analgesia (Paleti 2018 **Level II**, n=50, JS 4; Sapna 2013 **Level III-2**, n=124).

A single preoperative epidural dose of midazolam combined with ketamine in patients having a gastrectomy improved analgesia and prolonged the time to rescue analgesia vs epidural ketamine or placebo, with no significant adverse effects (Wang 2006 **Level II**, n=44, JS 4). Midazolam added to bupivacaine for epidural infusion improved analgesia but increased sedation (Nishiyama 2002 **Level II**, n=100, JS 1).

Midazolam has been added to caudal epidural analgesia in paediatric surgery, although age-related toxicity issues have not been addressed. In combination with bupivacaine, it prolongs postoperative analgesia (Kumar 2005 **Level II**, n=80, JS 5; Ansermino 2003 **Level I**, 2 RCTs [midazolam], n=60). In infants having hernia repairs, neither midazolam nor fentanyl added to bupivacaine for caudal anaesthesia improved postoperative analgesia or recovery (Baris 2003 **Level II**, n=75, JS 4).

4.13.2 | Neostigmine

Neostigmine acts as a spinal analgesic by potentiation of muscarinic cholinergic activity. In a literature review of animal and human studies, there was no evidence of neurotoxicity with spinal neostigmine (Hodgson 1999 **NR**).

4.13.2.1 | Neuraxial

Adding neostigmine to local anaesthetics (bupivacaine or ropivacaine) ± opioid for neuraxial administration in labour analgesia and postoperative analgesia after Caesarean section permits reduction of local anaesthetic doses (MD -4.08 mg/h; 95% CI -6.7 to -1.5) (Cossu 2015 **Level I**, 16 RCTs, n= 1,186). Only IT neostigmine (5 RCTs), but not epidural neostigmine (11 RCTs), increases risk of nausea (OR 9; 95%CI 4.7 to 17.1). Neuraxial neostigmine reduces risk of pruritus (OR 0.4; 95%CI 0.2 to 0.7) (6 RCTs), but does not increase hypotension, sedation or affect fetal outcome.

4.13.2.2 | Intrathecal

IT neostigmine for perioperative and peripartum analgesia prolongs the time to first analgesia request and results in a slight improvement in pain scores and a reduced need for rescue medication, however, it increases nausea and vomiting (OR 5.0; 95%CI 3.4 to 7.3), bradycardia requiring atropine (OR 2.7; 95%CI 1.4 to 5.4) and anxiety, agitation and restlessness (OR 10.3; 95%CI 3.7 to 28.9) (Ho 2005 **Level I**, 19 RCTs, n=1,019) (4 RCTs overlap with Cossu 2015). The authors conclude that the significant adverse effects outweighed any clinical benefit, a conclusion supported by another systematic review, where a lack of a clear dose-response is also identified (Habib 2006 **Level I,** 17 RCTs [IT neostigmine], n unspecified) (15 RCTs overlap).

Subsequent RCTs not included in these meta-analyses support their findings in principle. In patients having various types of surgery under spinal anaesthesia, IT neostigmine prolonged time to first analgesic request (Kayalha 2015 **Level II** n=68, JS 4; Akinwale 2012 **Level II**, n=60, JS 4) and/or effective postoperative analgesia (Kumari Vasantha 2018 **Level II** n=100, JS 4) and/or reduced analgesic consumption (Jain 2012 **Level II**, n=45, JS 4).

In patients having spinal anaesthesia, IT clonidine 75 mcg had longer time to first analgesic request (MD 62 min) but more hypotension during surgery vs IT neostigmine 50 mcg (Yoganarasimha 2014 **Level II**, n=50, JS 3). Both, IT clonidine 30 mcg and IT neostigmine 75 mcg increased the duration spinal analgesia, but neostigmine caused more nausea and vomiting (Bhar 2016 **Level II**, n=150, JS 4). In patients undergoing orthopaedic surgery under spinal anaesthesia, IT dexmedetomidine 5 mcg was superior to IT neostigmine 50 mcg due to faster onset of anaesthesia, better intra- and postoperative analgesia, and prolonged duration of motor and sensory blockade without significant increases in adverse effects (Singh 2017 **Level II** n=75, JS 4). After elective gynaecological surgery under spinal anaesthesia, IT neostigmine extended postoperative analgesia more than IT magnesium (Joshi-Khadke 2015 **Level II**, n=75, JS 4). After surgery for tibial fracture under spinal anaesthesia, IT neostigmine 150 mcg/bupivacaine vs IT fentanyl 25 mcg/bupivacaine and IT magnesium 50 mg/bupivacaine increased the incidence of hypotension, bradycardia, and nausea and vomiting, and failed to prolong duration of analgesia (Mokaram Dori 2016 **Level II**, n=210, JS 4).

Adverse events of IT neostigmine seem to be dose-dependent. In patients undergoing lower abdominal and lower limb surgery, IT neostigmine 150 mcg vs IT neostigmine 50 mcg as an adjuvant to bupivacaine 12.5 mg caused more nausea and vomiting (Pandey 2016 **Level II**, n=75, JS 4). IT neostigmine 75 mcg caused less nausea and vomiting than IT neostigmine 150 mcg when added to spinal anaesthesia for Caesarean section (Hye 2010 **Level II**, n=90, JS 4). Very low-dose IT neostigmine 1 mcg increased the duration of analgesia and decreased the analgesic consumption

over 24 h post-TKA with no increase in the incidence of adverse effects including nausea or vomiting. (Jain 2012 **Level II**, n=45, JS 4).

4.13.2.3 | Epidural

Epidural neostigmine in the general surgical and obstetric populations improves postoperative analgesia in most studies without increasing the incidence of adverse effects (Habib 2006 **Level I**, 7 RCTs [epidural neostigmine], n unspecified). Epidural neostigmine combined with an opioid reduces epidural opioid requirements but may not decrease opioid-related adverse effects vs the opioid alone (Walker 2002 **Level I**, 6 RCTs [neostigmine], n=370).

See Section 10.6.3.1 for use of neostigmine in paediatric caudal epidural analgesia.

4.13.2.4 | Other

Intra-articular administration of neostigmine produces a useful analgesic effect in the postoperative period and is not associated with an increase in the incidence of adverse effects (Habib 2006 **Level I**, 4 RCTs [intra-articular neostigmine], n unspecified).

Studies investigating the efficacy of adding neostigmine to the local anaesthetics used for brachial plexus block and IVRA report conflicting results (Habib 2006 **Level I,** 4 RCTs [perineural neostigmine], n unspecified).

4.13.3 | Botulinum toxin A

Botulinum toxin (botox) A is an exotoxin produced from clostridium botulinum (Sandrini 2017 **NR**; Shilpa 2014 **NR**). Following direct IM injection, botulinum toxin A irreversibly binds to the acetylcholine receptor inducing chemical denervation with resultant dose-dependent muscular paralysis. The extent and duration of paralysis depends on the dose administered. Systemic weakness may follow high cumulative doses. Reinnervation occurs over weeks to months. Botulinum toxin A does not interfere with acute pain perception, nor does it cause local anaesthesia. The use of botulinum toxin in the treatment of chronic painful conditions is beyond the scope of this section.

In treating pain and related muscle spasm in a range of conditions, botulinum toxin A is effective in reducing limb spasm (Son 2019 **Level I**, 27 RCTs, n=2,793; Dong 2017 **Level I**, 22 RCTs, n=1,804), but evidence relating to spasticity-related pain remains uncertain (Baker 2013 **Level I**, 10 RCTs [in pain], n=971). In a range of neuropathic pain conditions (eg trigeminal neuralgia), Botulinum toxin A reduces pain at 4 wk (MD -1.6/10; 95%CI -3.2 to -0.1), 12 wk (MD -1.5/10; 95%CI -2.1 to -0.9) and 24 wk (MD -1.6/10; 95%CI -2.8 to -0.4) (Meng 2018 **Level I**, 12 RCTs, n=495).

In subacute and chronic neck disorders with or without associated cervicogenic headache, IM botulinum toxin A injections provide no clear benefit (Langevin 2011 **Level I** [Cochrane], 9 RCTs, n=503). There is insufficient evidence for the use botulinum toxin A for the treatment of rare head and neck pain syndromes (cluster headache, chronic paroxysmal hemicrania, trigeminal neuralgia) with varying results from only a few small sized trials (cervicogenic headache, chronic neck pain, temporomandibular disorders) (Sycha 2004 **Level I**, 15 RCTs, n=721).

KEY MESSAGES

1. Intrathecal midazolam combined with a local anaesthetic improves and prolongs analgesia and reduces postoperative nausea and vomiting (**U**) (**Level I**).
2. Intrathecal neostigmine improves perioperative and peripartum analgesia in combination with other intrathecal medications (**S**) (**Level I**) but is associated with dose-dependent significant adverse effects, in particular nausea and vomiting (**Q**) (**Level I**).
3. Epidural neostigmine combined with local anaesthetics improves postoperative and peripartum analgesia without increasing the incidence of adverse effects (**U**) (**Level I**).
4. Epidural neostigmine combined with an opioid reduces the dose of epidural opioid that is required for analgesia (**U**) (**Level I**).

4.14 | Complementary and alternative medicine

Complementary and alternative medicine (CAM) is defined as healthcare practices outside the conventional dominant "orthodox" health system of Western industrialised society (Belgrade 2008 **NR**). The boundary between CAM and conventional medicine overlaps and changes with time. In some cultures, these therapies may be considered conventional mainstream practices.

CAM may be classified into two groups: as natural products, including but not limited to herbs, vitamins, minerals and probiotics, vs mind and body practices such as yoga, meditation, massage, acupuncture, tai chi, qi gong, chiropractic and osteopathic manipulation, hypnotherapy and others (NCCIH 2018 **GL**). Ayurvedic medicine, traditional Chinese medicine, homeopathy and naturopathy are considered CAM. CAM approaches are usually termed "alternative" when used in place of conventional medical treatments and "complementary" when used together. This section covers the use of natural products administered as analgesic medicines for treatment of acute pain only; good data on their use in this indication are limited.

See Section 10.11 for paediatric specific data.

4.14.1 | Vitamins

Several mechanisms have been described to explain the analgesic effect of Vitamin C (Carr 2017 **NR**).

Vitamin C reduces acute postoperative pain (Chaitanya 2018 **Level IV SR** [PRISMA], 4 RCTs & 3 studies, n=12,395) and has moderate evidence for a reduction of postoperative morphine consumption (Chen 2016 **Level I** [PRISMA], 7 RCTs [postoperative], n=854). In subsequent RCTs, oral Vitamin C 1 g/d decreased postoperative pain score and rescue analgesia requirements after foot and ankle surgery (Jain 2019 **Level II**, n=60, JS 5) and after major abdominal surgery vs placebo where Vitamin C 2 g was comparable to melatonin 6 mg (Tunay 2020 **Level II**, n=165, JS 5). In acute herpes zoster, concomitant Vitamin C infusion 5 g did not improve pain relief (Kim 2016 **Level II**, n=87, JS 2).

Vitamin B complex (comprising of thiamine [B1], riboflavin [B2], pyridoxine [B6] and nicotinamide) reduced pain intensity and analgesic consumption after Caesarean section when combined with gabapentin vs gabapentin alone (Khezri 2017 **Level II**, n=128, JS 4). Vitamin B complex (thiamine, pyridoxine and hydroxo- or cyanocobalamin) when combined with ketorolac 15 mg was as effective as ketorolac 30 mg monotherapy after Caesarean section (Beltran-Montoya 2012 **Level II**, n=100, JS 3) or more effective when combined with diclofenac 50 mg in relieving acute low back pain vs diclofenac monotherapy (Mibielli 2009 **Level II**, n=372, JS 5). Also in acute low back pain, combination diclofenac/vitamin B complex TPC (thiamine, pyridoxine, and cyanocobalamin) provides greater analgesia vs diclofenac monotherapy (OR 2.23; 95%CI 1.59 to 3.13) (Calderon-Ospina 2020 **Level I**, 4 RCTs, n=1,108). In patients with acute ophthalmic zoster, Vitamin B 12 1,000 mcg/lidocaine 20 mg SC daily for 12 d into the regions of the affected innervations of V1 achieved better pain relief vs controls (IM vitamin B 12, local lidocaine) (Xu 2016a **Level II**, n=98, JS 3; Xu 2016b **Level II**, n=204, JS 3).

4.14.2 | Herbal Medicines

A meta-analysis on oral homeopathic St John's wort *(Hypericum perforatum)* showed no significant benefit on dental pain; the meta-analysis was limited by marked heterogeneity and poor study quality (Raak 2012 **Level I** [QUOROM], 4 studies, n=325). A subsequent review on topical application of *Hypericum perforatum* found studies on improved pain relief for acute otitis media, herpes skin lesions and wound pain after Caesarean section and suggests that this may be due to its anti-inflammatory effects (Galeotti 2017 **NR**). Oral *Hypericum perforatum* affects the

metabolism of oxycodone through induction of cytochrome P450 3A (CYP3A) and leads to a significant reduction of plasma concentration and half-life reducing efficacy (Nieminen 2010 **Level II**, n=12, JS 3).

Homeopathic preparations of *Arnica montana* (containing sesquiterpenes) in acute postoperative pain have shown variable results. A systematic review and other studies concluded that homeopathic arnica vs placebo is not effective for pain relief after orthopaedic surgery (Roberts 2012 **Level I** [PRISMA], 3 studies (arnica), n=181), hallux valgus surgery (Karow 2008 **Level II**, n=88, JS 4) or abdominal hysterectomy (Hart 1997 **Level II**, n=93, JS 5). In contrast, homeopathic arnica vs placebo reduced pain after tonsillectomy (Robertson 2007 **Level II**, n=190, JS 5) (although a large number of patients in this study were lost to follow-up) and after varicose vein surgery (Wolf 2003 **Level II**, n=60, JS 5). A subsequent review (covering many of the studies above) concluded that arnica in homeopathic dilutions has high tolerability and may have effects in treating inflammation (Iannitti 2016 **NR**). The authors argue that variations in formulation affects the quantity of active sesquiterpenes and hence result in variable clinical effects. Traumeel S (an over-the-counter homeopathic highly diluted preparation of extracts from a combination of plants [including arnica] and minerals) was also ineffective following foot surgery (Singer 2010 **Level II**, n=80, JS 4).

A systematic review of the efficacy and safety of Damask rose *(Rosa damascena Mill*) suggests safe use with some pain relief in acute settings (3 RCTs) (Nayebi 2017 **Level I**, 12 RCTs, n=748). Although most of the studies compared topical or inhalational (aromatherapy) applications, one study used oral extract with greater pain relief after Caesarean section vs placebo. The Damask rose recipients also experienced a longer time to requesting rescue analgesia, with lower total analgesic consumption (Gharabaghi 2011 **Level II**, n=92, JS 3).

Zingiberaceae include turmeric (*Curcuma longa*), ginger (*Zingiber officinale*), Javanese ginger (*Curcuma zanthorrhiza*) and galangal (*Alpinia galanga*). Curcumin (diferuloyl methane) is the principal curcuminoid of Indian spice turmeric, while the anti-inflammatory components of ginger are gingerol and zingerone. Extracts of Zingiberaceae reduce pain intensity in a mix of acute and chronic pain states (SMD -0.67; 95%CI -1.13 to -0.21) (Lakhan 2015 **Level I** [PRISMA], 8 RCTs, n=734). Curcuminoids are effective in reducing pain vs a pooled control group of placebo or NSAID (SMD -0.57; 95%CI -1.11 to -0.03), but not vs either placebo or NSAID in a mix of acute and chronic pain states (Sahebkar 2016 **Level I** [PRISMA], 8 RCTs, n=606) (2 RCTs overlap). The effect was greater when a bioavailability enhancer such as piperine was administered (SMD -0.98; 95%CI -1.81 to -0.15); however, only three RCTs in the review evaluated the effectiveness of curcuminoids in acute pain and were not separately analysed. A combination nutritional supplement containing *Boswellia serrata* (30% boswellic acid) and *Curcuma longa* (95% curcuminoids) lowered pain and tramadol rescue requirements only in the first postoperative wk after arthroscopic supraspinatus tendon repair vs placebo (Merolla 2015 **Level II**, n=104, JS 3). A subsequent RCT found ginger powder 500 mg as effective as ibuprofen 400 mg and superior to placebo with regard to pain relief and rescue analgesic requirements POD 1 in patients after wisdom tooth extraction (Rayati 2017 **Level II**, n=67, JS 4).

There is weak evidence for a reduction of rescue analgesia requirements (RR 0.5; 95%CI 0.1 to 2.1) with use of Damask rose (*Rosa damascena*) and ginger vs placebo after laparoscopic and obstetric/gynaecological surgery (Arruda 2019 **Level III-1 SR** [PRISMA], 10 RCTs & 1 study, n=693).

A transdermal preparation of Fenugreek seeds 10% (*Trigonella foenum-graecum L*.) applied topically for open hernioplasty reduced pain intensity and rescue analgesics consumption vs placebo patch and in the first 6 h vs diclofenac patch (Ansari 2019 **Level II**, n=90, JS 4).

Saffron (*Crocus sativus*) 250 mg as a syrup taken together orally with date-juice vs saffron with artificial sugar and placebo reduced pain intensity and anxiety during labour in primiparous women (Mohammadierad 2018 **Level II**, n=96, JS 5).

Herbal medicines (White willow bark [*Salix alba*] and Devil's claw [*Harpagophytum procumbens*]) for non-specific low-back pain (a mix of acute, subacute and chronic back pain) result in short-term improvement vs placebo (Gagnier 2016 **Level I** [Cochrane], 14 RCTs, n=2,050). The review also reported on the effectiveness of several topical preparations of herbal plaster and ointment-based applications including Cayenne (*Capsicum frutescens*), Comfrey root extract (*Symphytum officinale*) and Brazilian arnica (*Solidago chilensis*). However, the quality of evidence was poor. Side effects were usually mild and transient.

Herbal and dietary supplement combinations are commonly prescribed in CAM treatment. A study using a mixture of homoeopathic preparations (arnica, *Bryonia alba, Hypericum perforatum, Ruta graveolens*) did not show any benefit in postoperative pain relief and morphine consumption after knee ligament reconstruction surgery (Paris 2008a **Level II**, n=158, JS 4). There is also no clear evidence that the combination of oral arnica with *Hypericum perforatum* is effective in pain relief after dental procedures (Galeotti 2017 **NR**). Another herbal combination consisting of anise (*Pimpinella anisum*), celery (*Apium graveolens*) and saffron (*Crocus sativus*) (referred to as PAC), had greater pain reduction and faster onset in patients with post-partum pain vs mefenamic acid in a single-blind study (Simbar 2015 **Level II**, n=108, JS 2).

Puerarin, a Chinese herb extract, was analgesic and anti-inflammatory for burns dressing changes; however, the control group received no analgesia (Zhang 2013 **Level II**, n=32, JS 5).

Rhubarb combined with trypsin inhibitor versus trypsin inhibitor alone improved outcomes of acute pancreatitis including abdominal pain (Hu 2018b **Level I**, 16 RCTs, n=912).

Probiotics reduce the pain and symptom severity in IBS vs placebo (Didari 2015 **Level I**, 15 RCTs, n=1,793).

For dysmenorrhoea, a Cochrane review investigated twelve different herbal medicines German chamomile (*Matricaria chamomilla, M recutita, Chamomilla recutita*), cinnamon (*Cinnamomum zeylanicum, C. verum*), Damask rose (*Rosa damascena*), dill (*Anethum graveolens*), fennel (*Foeniculum vulgare*), fenugreek (*Trigonella foenum-graecum*), ginger (*Zingiber officinale*), guava (*Psidium guajava*), rhubarb (*Rheum emodi*), uzara (*Xysmalobium undulatum*), valerian (*Valeriana officinalis*), and zataria (*Zataria multiflora*) and five non-herbal supplements (fish oil, melatonin, vitamins B1 and E, and zinc sulphate) in a variety of formulations and doses (Pattanittum 2016 **Level I** [Cochrane], 27 RCTs, n=3,101). Very limited evidence of effectiveness vs placebo or no treatment was found for fenugreek (1 RCT, n=101), fish oil (1 RCT, n=120), fish oil plus vitamin B1 (1 RCT, n=120), ginger (4 RCTs, n=335), valerian (1 RCT, n=100), vitamin B1 alone (1 RCT, n=120), zataria (1 RCT, n=99), and zinc sulphate (1 RCT, n=99). Very limited evidence was found that chamomile was more effective than NSAIDs (1 RCT, n=160), while no difference vs NSAIDs was found for dill (1 RCT, n=47), fennel (1 RCT, n=59), guava (1 RCT, n=155), rhubarb (1 RCT, n=45), valerian (1 RCT, n=99) and Damask rose (1 RCT, n=92). Comparisons between CAM for dysmenorrhoea showed that Vitamin B1 may be more effective than fish oil (1 RCT, n=120). Subsequent systematic reviews emphasise again the limited quality of the evidence, the high risk of bias and the difficulties to draw definitive conclusions on efficacy. One systematic review analysed results for fennel (*Foeniculum vulgare*) (4 RCTs, n=295), chamomile (*Matricaria chamomilla)* (3 RCTs, n=220) and zataria (*Zataria multiflora*) (3 RCTs, n=302) (Sharghi 2019 **Level I**, 17 RCTs, n=1,656). Another identified only one RCT with low risk of bias to be considered supportive evidence for use of Damask rose (*Rosa damascena*) (Pellow 2018 **Level I** [PRISMA], 22 RCTs, n=1,937).

4.14.3 | Aromatherapy

Aromatherapy describes the inhalation (or sometimes administration to the skin) of essential oils as part of herbal medicine, possibly affecting emotions through the neuroendocrine and autonomic nervous system.

Aromatherapy (oil inhalation and oil massage) reduces pain of dysmenorrhoea vs no treatment or placebo treatment; however, there is a high risk of bias weakening these results (Lee 2018d **Level III-1 SR**, 19 studies, n=1,787; Song 2018 **Level III-3 SR** [PRISMA], 9 RCTs & 12 studies, n=1,580) (13 studies overlap).

There is no sufficient evidence to support the use of aromatherapy for the treatment of postoperative pain (Dimitriou 2017 **Level I**, 9 RCTs, n=644).

Aromatherapy may reduce pain, anxiety and improve sleep quality in burns patients, but the low quality of trials with regard to randomisation and bias does not permit a conclusion (Choi 2018 **Level I** [PRISMA], 4 RCTs, n=248). The addition of aromatherapy (lavender) to standard treatment of renal colic with parenteral diclofenac improved pain scores at 30 min, but only in female patients (Irmak Sapmaz 2015 **Level II**, n=100, JS 0).

4.14.4 | Melatonin

An experimental study on volunteers observed a dose dependent effect on pain threshold and pain tolerance after sublingual melatonin 0.15 mg/kg or 0.25 mg/kg vs placebo (Stefani 2013 **Level II EH**, n=61, JS 5). Two preoperative melatonin doses of 5 mg led to lower pain and anxiety scores in the first 24 h (NNT 2.20 and 2.53) and reduced IV PCA morphine usage after abdominal hysterectomy (Caumo 2007 **Level II**, n=35, JS 5). Melatonin 6 mg vs Vitamin C 2 g both reduced pain and patient-controlled morphine consumption and supplementary doses of diclofenac in patients after major abdominal surgery vs placebo (Tunay 2020 **Level II**, n=165, JS 5). Melatonin reduced pain during blood taking in children vs placebo (Marseglia 2015 **Level II**, n=60, JS 5).

4.14.5 | Honey

Oral administration of honey has been associated with improved pain relief (3 RCTs, n=201) and reduced need for analgesic intake after tonsillectomy in children vs placebo, especially in the early postoperative period based on RCTs of poor methodological quality (Lal 2017 **Level I** [PRISMA], 8 RCTs, n=545; Hwang 2016 **Level I**, 4 RCTs, n=264) (4 RCTs overlap). An RCT not included in the meta-analyses found that onset to pain relief was faster, pain severity was lower and the need for rescue analgesia was less in the honey recipients vs controls (Mohebbi 2014 **Level II**, n=80, JS 2).

KEY MESSAGES

1. White willow bark (*Salix alba*) and devil's claw (*Harpagophytum procumbens*) are effective in treating acute episodes of low back pain (**U**) (**Level I** [Cochrane Review])
2. A variety of complementary medicines may show efficacy in prevention and treatment of primary dysmenorrhoea based on very limited evidence (**W**) (**Level I** [Cochrane Review]), including aromatherapy (**N**) (**Level III-1 SR**).
3. Curcuminoids and extracts of Zingiberaceae may reduce pain intensity in acute and chronic pain states compared to placebo (**N**) (**Level I** [PRISMA]).
4. Oral administration of honey versus control reduces postoperative pain and analgesic use after tonsillectomy (**N**) (**Level I** [PRISMA]).
5. Vitamin C reduces postoperative opioid requirements (**N**) (**Level I** [PRISMA] and postoperative pain compared to placebo (**N**) (**Level IV SR** [PRISMA]).
6. Aromatherapy (**N**) (**Level I**), homeopathic preparations of arnica (*Arnica montana*) (**U**) (**Level I** [PRISMA]) and St John's wort (*Hypericum perforatum*) are not effective in treating acute postoperative pain (**U**) (**Level I** [QUOROM]).
7. St John's wort (*Hypericum perforatum*) induces metabolism of oxycodone reducing its plasma concentrations and efficacy (**U**) (**Level II**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ There is some evidence that some complementary and alternative medicines may be effective in some acute pain states. Adverse effects and interactions with medications have been described with complementary and alternative medicines and must be considered before their use (**U**).

☑ The evidence on complementary and alternative medicines is characterised by small sample sizes and study designs prone to bias and caution is urged in interpreting results. Additionally, the safety and potential drug interactions of many complementary and alternative medicines have not been adequately assessed **(N).**

Administration of analgesic medicines

Section Editor:
Prof Stephan A Schug

5.0 | Administration of analgesic medicines

Analgesic medicines can be administered by a number of different routes, either relying on a systemic or local effect or a combination of both. The choice of route may be determined by various factors, including the aetiology, severity, location and type of pain, the patient's overall condition and the characteristics of the chosen administration technique. Additional factors to consider with any route of administration are ease of use, accessibility, speed of analgesic onset, reliability of effect, duration of action, patient acceptability and cost.

The principles of individualisation of dose and dosing intervals apply to the administration of all analgesic agents, particularly opioids, by any route. A lack of flexibility in dose schedules has often meant that intermittent and prn (as needed) methods of pain relief have been ineffective when the routes of administration discussed below have been used (Bandolier 2003 **NR**). Frequent assessment of the patient's pain and their response to treatment (including the occurrence of any adverse effects) rather than strict adherence to a given dosing regimen is required if adequate analgesia is to be obtained.

Sections 5.1 to 5.5 below relate to opioids, paracetamol, nsNSAIDs and coxibs. For information relating to oral, parenteral and regional routes of administration of adjuvant medicines, refer to Sections 4.6 to 4.12.

Sections 5.6 to 5.9 below relate to routes of administration involving techniques of regional and local analgesia.

5.1 | Oral and sublingual route

Oral administration of analgesic agents is simple, non-invasive, has good efficacy in most settings and has high patient acceptability. Other than in the treatment of severe acute pain and providing there are no contraindications to its use, it is the route of choice for the administration of most analgesic medicines (Chou 2016 **GL**).

Limitations to the oral route include vomiting or delayed gastric emptying, when absorption is likely to be impaired. If multiple doses of an oral analgesic medicine are given before return of normal gastric motility, accumulated doses may enter the small intestine at the same time once emptying resumes ("*dumping effect*"). This could result in an unexpectedly large systemic uptake of the medicine and an increased risk of adverse effects.

Rates of absorption will vary according to the formulation of the oral analgesic agent (eg tablet, suspension, slow release [SR] preparation). Bioavailability will also vary between medications because of the effects of first-pass hepatic metabolism following uptake into the portal circulation. Titration of pain relief with oral analgesic medicines is slower compared with some of the other routes of administration discussed below.

Direct comparisons between oral opioid and nonopioid analgesics, or between oral and other routes of administration, are limited. Indirect comparisons, where the individual medications have been compared with a placebo, have been used to generate a "*league table*" of analgesic efficacy (see Table 5.1). This table is based on randomised, double-blind, single-dose studies or meta-analyses of such studies in patients with moderate to severe pain and shows the number of patients that need to be given the active medication to achieve at least 50% pain relief in one patient compared with a placebo ($NNT_{50\%}$) over a 4 to 6 h treatment period (Moore 2015 **Level I** [Cochrane], ≈460 RCTs, n≈50,000; Moore 2011 **Level I** [Cochrane], ≈350 RCTs, n≈45,000; Moore 2003 **Level I**, unspecified number of RCTs, n unspecified).

The validity of this approach as a true method of comparison of medicines may be questioned as there is no standardisation of the acute pain model or patient and only single doses of the analgesic agents are used. The effects of the analgesics may vary with different pain models (Gray 2005 reanalysing Barden 2004 **Level I**, 43 RCTs [paracetamol], n unspecified). However, it may be reasonable, in some circumstances, to extrapolate estimates of analgesic efficacy from one pain model to another (Barden 2004 **Level I**, 43 RCTs [paracetamol], n unspecified). Note for example that Ketoprofen 25 mg has a better $NNT_{50\%}$ of 2.0 (95% CI 1.8 to 2.3) than Ketoprofen 50mg $NNT_{50\%}$ 3.3 (95% CI 2.7 to 4.3) suggesting that significant caution should be undertaken comparing data in this way.

Table 5.1 | Table of analgesic efficacy (in all types of surgery)

Analgesic medication* and dose (mg)	Number of patients in comparison	$NNT_{50\%}$	Lower 95% confidence interval	Higher 95% confidence interval
Paracetamol + Ibuprofen 1000/400	543	1.5	1.4	1.7
Paracetamol + Ibuprofen 500/200	508	1.6	1.5	1.8
Dipyrone 1,000	113	1.6	1.3	2.2
Etoricoxib 120	798	1.8	1.7	2.0

**oral route unless otherwise specified*

*Source: Compiled with data from Moore 2003 (**Level I**, unspecified number of RCTs, n unspecified), Moore 2011 (**Level I** [Cochrane], ≈350 RCTs, n≈45,000) and Moore 2015 (**Level I** [Cochrane], ≈460 RCTs, n≈50,000). Formulations and doses not approved for use in Australia, New Zealand, Europe, USA or Canada have been removed from the table.*

5.1.1 | Paracetamol

Single doses of paracetamol are effective in the treatment of postoperative pain. The NNTs for a variety of doses, as well as combinations of paracetamol with other analgesic medicines such as ibuprofen, oxycodone, tramadol and codeine, are listed in Table 5.1.

There is no good evidence for a dose-dependent analgesic effect of oral paracetamol; the effects of 500 mg ($NNT_{50\%}$ 3.5; 95%CI 2.7 to 4.8), 600/650 mg ($NNT_{50\%}$ 4.6; 95%CI 3.9 to 5.5) and 1,000 mg ($NNT_{50\%}$ 3.6; 95%CI 3.2 to 4.1) show no statistically significant difference (Moore 2015 **Level I** [Cochrane], 53 RCTs, n=5,679).

The oral bioavailability of paracetamol is good at between 63 and 89% (Oscier 2009 **NR**). However, rate of absorption and peak concentrations are reduced by factors such as recent food intake (Moore 2015 **SR**), pregnancy (Raffa 2014 **NR**), opioid administration (Raffa 2018 **BS**) and high altitude (Idkaidek 2019 **EH**). Early postoperative oral administration can result in plasma concentrations that can vary enormously after the same dose and may remain subtherapeutic in some patients (Holmer Pettersson 2004 **PK**), however there does not appear to be a clinical difference of oral vs IV paracetamol in total hip arthroplasty (THA) and total knee arthroplasty (TKA) (Sun 2018 **Level I** [PRISMA], 2 RCTs, n=236; Westrich 2019 **Level II**, n=154, JS 5), Caesarean section (Wilson 2019 **Level II,** n=141, JS 3) or laparoscopic cholecystectomy (Plunkett 2017 **Level II**, n=60, JS 4).

Paracetamol effervescent tablets are absorbed significantly faster than ordinary paracetamol (Rygnestad 2000 **PK**).

5.1.2 | Nonselective NSAIDs and coxibs

A number of nsNSAIDs and coxibs have been shown to be effective as sole therapy in a variety of acute surgical pain settings. The NNTs of each of these medicines is listed in Table 5.1.

In general, there is no good evidence that NSAIDs given parenterally or rectally are more effective, or result in fewer adverse effects, than the same NSAID given orally for the treatment of postoperative pain (Tramer 1998 **Level I**, 26 RCTs, n=2,225). Only in the treatment of renal colic do IV NSAIDs result in more rapid analgesia. Only rectal NSAIDs are effective for reducing post ERCP pancreatitis (Serrano 2019 **Level I** [PRISMA], 21 RCTs, n=6,854).

The formulation of oral NSAIDs such as diclofenac seems to significantly impact their efficacy (Derry 2015b **Level I** [Cochrane], 18 RCTs, n=3,714). For the same 50 mg dose, diclofenac sodium has an $NNT_{50\%}$ of 6.6 (95%CI 4.1 to 17) vs diclofenac potassium an $NNT_{50\%}$ of 2.1 (95%CI 1.9 to 2.5) and diclofenac fast acting (dispersible products, solutions, and softgel formulations) an $NNT_{50\%}$ of 2.4 (95%CI 2.0 to 3.0).

5.1.3 | Conventional and atypical opioids

Oral opioids can be as effective in the treatment of acute pain as opioids given by other more invasive routes, if equianalgesic doses are administered (Cheung 2017 **NR**; Chou 2016 **GL**; Macintyre 2015 **NR**). Both IR and SR formulations have been used. In a number of postoperative settings combinations of SR and IR opioids have been used successfully without any parenteral opioids to treat acute pain after ENT surgery (Pogatzki-Zahn 2013 **Level IV**, n=275), spine surgery (Rajpal 2010 **Level IV**, n=200), cardiac surgery (Ruetzler 2014 **Level II**, n=51, JS 2) and orthopaedic surgery (Lamplot 2014, **Level II**, n=36, JS 2}).

When opioids are prescribed for the treatment of acute pain, consideration should be given to duration of therapy. In most cases short-term use only of these medicines is warranted. Discharge planning must consider the duration of use of opioids prescribed for the short-term management of acute pain and the weaning of those medicines and, in a small minority of patients, the potential for prescribed opioids to be abused or misused (see Section 8.13).

5.1.3.1 | Immediate-release formulations

The NNTs for various IR opioids are listed in Table 5.1.

PO doses of morphine and oxycodone IR have an onset of analgesic effect at around 30 min with a peak at 1 to 2 h (Hoeben 2012 **EH**).

The effectiveness of the different PO conventional and atypical opioids may change with the addition of paracetamol and NSAIDs:

- PO codeine in a single dose of 60 mg is not an effective analgesic agent after a variety of operations ($NNT_{50\%}$ 12) (Moore 2015 **Level I** [Cochrane], 33 RCTs, n=2,411). The effect was even smaller in the subgroup after dental surgery ($NNT_{50\%}$ 21) (Derry 2010 **Level I** [Cochrane], 15 RCTs, n=1,146). Combined with PO paracetamol, a significant dose response was seen with $NNT_{50\%}$ of 2.2 for paracetamol 800−1,000 mg/codeine 60 mg, 3.9 for paracetamol 600−650 mg/codeine 60mg, and 6.9 for paracetamol 300 mg/codeine 30 mg, and the combination extended the duration of analgesia by 1 h compared with paracetamol alone (Toms 2009 **Level I** [Cochrane] 26 RCTs, n=2,295). There are no data on combinations of PO paracetamol with low codeine doses <30 mg. A PO combination of paracetamol 500 mg/hydrocodone 5 mg did not provide superior analgesia to paracetamol 300 mg/codeine 30 m for extremity pain after ED discharge (Chang 2014 **Level II**, n=240, JS 5).

However, codeine 25.6 to 60 mg barely improves the analgesic efficacy of 400 mg ibuprofen in a number of combinations (Derry 2015a **Level I** [Cochrane], 6 RCTs, n=1,342).

- PO oxycodone IR in a single dose of 5 mg shows no benefit over placebo for the treatment of moderate to severe acute pain (Gaskell 2009 **Level I** [Cochrane], 3 RCTs [oxycodone 5 mg], n=317); doses of 15 mg ($NNT_{50\%}$ 4.6) (2 RCTs [oxycodone 15 mg], n=228) and in combination 5 mg oxycodone/325 mg paracetamol ($NNT_{50\%}$ 5.4) (3 RCTs [combination], n=388), 10 mg oxycodone/650 mg paracetamol ($NNT_{50\%}$ 2.7) (10 RCTs [combination], n=1,043) and 10 mg oxycodone/1,000 mg paracetamol ($NNT_{50\%}$ 1.8) (2 RCTs [combination], n=289) are more effective than placebo. Similar benefits are achieved by combining 5 mg oral oxycodone with 400 mg ibuprofen ($NNT_{50\%}$ 2.3) (Derry 2013 **Level I** [Cochrane], 3 RCTs, n=1,303).
- PO tramadol IR is an effective analgesic agent for postoperative pain with $NNT_{50\%}$ of 7.1 for 50 mg, 4.8 for 100 mg and 2.4 for 150 mg (Moore 1997 **Level I**, 18 RCTs, n=3,453). The combination of tramadol 75 mg or 112.5 mg with paracetamol 560 mg or 975 mg is more effective than either of its two components administered alone (McQuay 2003 **Level I**, 7 RCTs, n>1,400).
- After 3rd molar surgery, a meta-analysis of predominantly PO tramadol showed it is less effective and associated with more adverse events (MD 21.8%; 95%CI 13.8 to 29.9) than predominantly PO NSAIDs (Isiordia-Espinoza 2014 **Level I**, 4 RCTs, n=426 [oral] & n=51 [IM]).
- In women undergoing Caesarean section under single shot spinal anaesthesia with IT fentanyl, the regular administration of oral paracetamol, ibuprofen and tramadol resulted in lower pain scores (2.8 ± 0.84 vs 4.1 ± 0.48), higher satisfaction rate (9.1 ± 1.2 vs 8.3 ± 1.5), and more breastfeeds (23.7 ± 6.5 vs 19.2 ± 6.2) vs prn administration (Yefet 2017 **Level II**, n=200, JS 3).
- PO morphine IR is effective in the treatment of acute pain. Following preloading with IV morphine, oral morphine liquid 20 mg (initial dose 20 mg; subsequent doses increased by 5 mg if breakthrough doses needed) every 4 h with additional 10 mg doses prn provided better pain relief after hip surgery than IM morphine 5 to 10 mg prn (McCormack 1993 **Level II**, n=47, JS 5).
- In comparison with IV PCA morphine alone, administration every 4 h of 20 mg but not 10 mg of PO morphine reduced PCA morphine consumption; however, there were no differences in pain relief or adverse effects (Manoir 2006 **Level II**, n=63, JS 5).
- PO tapentadol and PO oxycodone have been compared mostly postoperatively using total pain relief over 48 h. Tapentadol IR 50 mg (MD -2.83/100; 95% CI-11.8 to 6.14) (3 RCTs, n=1,003) and 75 mg (MD -0.92/100; 95% CI -9.15 to 7.32) (2 RCTs, n=885) have efficacy similar to oxycodone IR 10 mg, while 100 mg is superior (MD 9.4/100; 95% CI 2.56 to 16.24) (1 RCT, n=175) (Xiao 2017 **Level I** [PRISMA], 9 RCTs, n =3,961). Regarding adverse events, there was less constipation with 50 mg (RR 0.44; 95%CI 0.21 to 0.93) and 75 mg (RR0.37; 95% CI 0.24 to 0.59), less nausea with 50 mg (RR 0.64; 95%CI 0.48 to 0.85) and 75 mg (0.61; 95%CI 0.41 to 0.93), but more somnolence with 100 mg (RR 1.67; 95%CI 1.08 to 2.58). Overall side effects were only lower in the 75 mg group (RR 0.88; 95%CI 0.83 to 0.94) although the 50 mg group had less discontinuations due to side effects (RR 0.52; 95%CI 0.35 to 0.77).
- SL (11 RCTs, n=1,111) and IV or IM buprenorphine show similar analgesic efficacy overall (pain scores 1–48 h) (23 RCTs) and side effects including respiratory depression (OR 2.07; 95% CI 0.78 to 5.51) (10 RCTs [respiratory rate <8-12 bpm]), sedation (10 RCTs), nausea (21 RCTs) and vomiting (13 RCTs) to morphine (IV, IV-PCA, IM, PO), but with less pruritus (6 RCTs) (White 2018 **Level I**, 28 RCTs, n=2,210). See Section 4.3.1.3 for detail.

IR oral opioids such as oxycodone, morphine and tramadol have also been used as 'step-down' analgesia after PCA, with doses based on prior PCA requirements (Macintyre 2015 **NR**) and after epidural analgesia (Lim 2001 **Level II**, n=101, JS 5).

5.1.3.2 | Slow-release formulations

The role of slow release (SR) formulations (also referred to as controlled-release, extended-release or prolonged-release) in acute pain is controversial. ANZCA has published a position statement indicating their use should be avoided except on a short-term basis for post-operative and post-traumatic analgesia where pain is prolonged (ANZCA 2018 **GL**), which has been discussed extensively in the literature (Stevens 2020 **NR**; Levy 2019 **NR**). This recommendation is also in line with multiple international guidelines (FDA 2012 **GL**; Webster 2015 **GL**; Chou 2016 **GL**; Dowell 2016 **GL**; Clarke 2020 **GL**; Levy 2020 **GL**). When SR formulations are used, consideration should then be given to opioids with the least sedative (and therefore respiratory depressant) effect such as the atypical opioids tramadol, tapentadol and transdermal buprenorphine (ANZCA 2018 **GL**).

Concerns regarding the use of SR formulations include:

- SR formulations are not registered for acute pain by most regulatory authorities including the TGA, the FDA and the EMA.
- SR formulations vary widely in time to peak plasma concentrations with many being in the 3 to 6 h range. In contrast and in most cases, the analgesic effect of the IR opioid preparations will be seen within about 40 to 60 min. Rapid titration to effect is therefore easier and more appropriate with IR formulations.
- There is an increased risk of OIVI with use of SR formulations in an acute setting (Levy 2019 **NR**). This has been shown specifically for SR oxycodone >10 mg after TKA (Weingarten 2015 **Level IV**, n=11,970). There is also an increased risk of unintentional overdose with all SR opioid use (not differentiating conventional from atypical opioids) in chronic pain (Miller 2015 **Level III-2**, n= 840,606). This risk was particularly high during the first 2 weeks after initiation of treatment (HR 5.25; 95%CI 1.88 to 14.72), relevant to the acute setting. An analogy is the increased OIVI incidence with continuous infusions of opioids (Schug 1993 **Level IV**, n=3,016) and with PCA use with a continuous background infusion (George 2010 **Level I**, 12 RCTs [adults], n=674) (see also Section 6.4.3). It is of note here that regularly (instead of prn) administered IR opioids would raise similar concerns.
- Where patients are taking SR formulations at home for acute pain there is concern about the ability of the patient to down titrate medications if their pain resolves faster than expected by the prescriber, which given the variability of pain is not an unlikely event (Stevens 2020 **NR**; ANZCA 2018 **GL**; Macintyre 2015 **NR**). A retrospective analysis of US healthcare data found high rates of continued use at 1 y (27.3%) and 3 y (20.5%) in opioid naïve patients when the initial opioid prescribed was a SR opioid (Shah 2017 **Level IV**, n=1,294,247). However, it is unclear how many of these prescriptions were intentional initiations of medication for chronic pain.

Possible benefits with use of SR formulations (ideally atypical opioids) may exist in certain settings of acute pain by providing more regular analgesia ie:

- Regular analgesia may be more effective than prn only analgesia in some circumstances. Post LSCS under spinal anaesthesia, patients randomised to receive regular paracetamol, diclofenac and IR tramadol (note: an atypical opioid with reduced risk of OIVI [see Section 4.3.1.3]) had lower pain, better satisfaction, more breast feeding and less infant formula use than patients prescribed the same medications as prn (Yefet 2017 **Level II**, n=214, JS3).

- Some SR formulations may have a better tolerability profile. For example, SR tramadol formulations have lower adverse events vs IR tramadol in the treatment of chronic pain due to osteoarthritis (Langley 2010 **Level III-II SR**, 15 studies, n unspecified).
- Where opioids are being regularly administered due to the severity of the pain caused by surgery or trauma, SR opioids may have a limited role. Using SR oxycodone in titrated doses during rehabilitation after TKA improved pain control and functional rehabilitation and reduced LOS at the rehabilitation hospital. However, it is of concern that SR oxycodone use in this setting was associated with 4 times higher overall opioid use (total daily consumption of oxycodone [SR and IR] 54.4 vs 12.9 mg) (Cheville 2001 **Level** II, n=59, JS 5). The latter finding highlights reasons for caution with SR opioid use in such a setting, even where possibly indicated (Stevens 2020 **NR**).

SR opioid preparations should only be used at set time intervals and IR opioids should be used prn for acute pain exacerbations, and for titration of SR opioids. In this context it is of note, that the position paper by ANZCA regards methadone and transdermal fentanyl, due to their long half-life, as behaving similarly to SR opioids (ANZCA 2018 **GL**).

SR oxycodone is an effective component in the immediate management of acute pain (Kampe 2004 **Level II**, n=40, JS 5; Sunshine 1996 **Level II**, n=182, JS 5). However, IR oxycodone and paracetamol 325 mg given every 6 h led to better pain relief than 10 mg SR oxycodone given every 12 h (Kogan 2007 **Level II**, n=120, JS 5). In comparison with IV morphine PCA alone, SR oxycodone in addition to morphine PCA resulted in improved pain relief and patient satisfaction after lumbar discectomy and a lower incidence of nausea and vomiting, as well as earlier return of bowel function (Blumenthal 2007 **Level II**, n=40, JS 5). SR oxycodone was found to be effective as 'step-down' analgesia after 12–24 h of PCA morphine (Ginsberg 2003 **Level IV**, n=189). However after TKA/THA, the addition of SR morphine 30 mg twice daily to usual care resulted in only minimally improved analgesia but increased adverse effects (Musclow 2012 **Level II**, n=200, JS 5). Similarly, addition of preoperative SR oxycodone to a multimodal analgesia regimen increased pain intensity and opioid requirements and impaired early mobilisation on POD 1 (Cooper 2019 **Level III-3**, n=550).

The addition of oral naloxone to oral opioids results in less constipation in the setting of chronic pain (Nee 2018 **Level I** [PRISMA], 5 RCTs, n=838). While it was suggested that these benefits were transferable to acute pain settings (Kuusniemi 2012 **NR**), a difference was not found after laparoscopic hysterectomy (Comelon 2013 **Level II**, n=85, JS 5) or TKA (Oppermann 2016 **Level III-2**, n=80) but time to first bowel motion was improved after colorectal surgery (Creamer 2017 **Level II**, n=82, JS 3).

Comparing PO SR tapentadol 50 mg with SR oxycodone 10 mg/naloxone 5mg after orthopaedic trauma surgery found similar quality of analgesia (3.8 ± 1.9 vs 3.8 ± 2.1) and minor adverse effects (51% vs 49%; 95%CI for difference −8 to 14%) (Haeseler 2017 **Level II,** n=266, JS 2). In non-breastfeeding women undergoing Caesarean section with IT morphine, SR tapentadol 50 mg was inferior to SR oxycodone 10 mg in terms of summed pain intensity difference (SPID) at 36 h (MD -13.77; 95%CI -26.1 to -1.42) but not at 48 h, and with no difference in other analgesic outcomes or patient satisfaction at 36 or 48 h (Ffrench-O'Carroll 2019 **Level II**, n=68, JS 3). There was an increased time to rescue medication with SR oxycodone. Side effects were common and similar in quantity between SR tapentadol and SR oxycodone (70 vs 71%), although more oxycodone recipients received intraoperative antiemetic prophylaxis vs tapentadol recipients (71 vs 42%) including dexamethasone (43% vs 24%).

KEY MESSAGES

1. Oral combinations of paracetamol/ibuprofen provide superior analgesia to paracetamol/codeine; both combinations are more effective than the individual medicines and have a dose-response effect (**S**) (**Level I** [Cochrane Review]).
2. Oral combinations of paracetamol/tramadol are more effective than the individual medications and have a dose-response effect (**U**) (**Level I**).
3. NSAIDs given parenterally or rectally are not more effective and do not result in fewer adverse effects than the same medicines given orally (**U**) (**Level I**).
4. The formulation of oral NSAIDs (eg fast acting [dispersible, solution or gel], sodium versus potassium salt) can greatly affect their efficacy (**N**) (**Level I**).
5. Early postoperative oral administration of paracetamol results in highly variable plasma concentrations that may remain subtherapeutic in some patients (**U**) (**Level II**). However, no difference in clinical efficacy to intravenous administration is seen in hip and knee arthroplasty (**N**) (**Level I**), Caesarean section (**N**) (**Level II**) or laparoscopic cholecystectomy (**N**) (**Level II**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Other than in the treatment of severe acute pain, and providing there are no contraindications to its use, the oral route is the route of choice for the administration of most analgesic medicines (**U**).

☑ Slow-release opioid preparations (particularly conventional opioids including transdermal fentanyl and methadone) are not recommended in general for the management of acute pain in opioid-naïve patients due to difficulties in short-term dose adjustments needed for titration, an increased risk of opioid-induced ventilatory impairment and risk of initiating long-term use (**S**). In some patients with prolonged postoperative and post-traumatic acute pain states, the use of slow-release opioid preparations may be appropriate on a short-term basis with preference for use of atypical opioids (**N**).

☑ Slow-release oral opioid preparations should only be given at set time intervals (**U**).

5.2 | Intravenous route

Analgesic medicines given by the IV route have a more rapid onset of action compared with most other routes of administration.

5.2.1 | Paracetamol

IV paracetamol 1,000 mg is an effective analgesic after surgery with an $NNT_{50\%}$ of 4.0 (95%CI 3.5 to 4.8) over 4 h and an $NNT_{50\%}$ of 5.3 (95%CI 4.2 to 6.7) over 6 h (Tzortzopoulou 2011 **Level I** [Cochrane], 36 RCTs, n=3,896). As an adjunct to opioid analgesia, opioid requirements are reduced by 30% over 4 h after a single IV dose. For orthopaedic surgery specifically, IV paracetamol has similar benefits (Jebaraj 2013 **Level I** [PRISMA], 8 RCTs, n unspecified). After Caesarean section, IV paracetamol reduces opioid consumption (SMD -0.46; 95%CI -0.83 to -0.09) and pain (SMD -0.72; 95%CI -1.31 to -0.13) (Ng 2019 **Level I** [PRISMA], 7 RCTs, n=467).

IV paracetamol perioperatively reduces PONV when administered before incision and to a lesser extent before recovery from anaesthesia (Apfel 2013 **Level I** [PRISMA], 30 RCTs, n=2,364). This effect is correlated to pain relief achieved but not to reduced opioid consumption. IV paracetamol given within 1 h prior to incision is more effective than post incision in reducing pain at 1 h (MD -0.50; 95%CI -0.98 to -0.02) and 2 h (MD -0.34; 95%CI - 0.67 to -0.01), 24 h opioid consumption (SMD of -0.52; 95% CI -0.98 to -0.06) and PONV (RR 0.50; 95%CI 0.31 to 0.83) (Doleman 2015 **Level I** [PRISMA], 7 RCTs, n=544).

Dosing of IV paracetamol in bariatric patients remains undefined; in a study of adolescents and young adults undergoing bariatric surgery (mean BMI 46) plasma concentrations of paracetamol were undetectable 2 h after 1,000 mg dosing (Hakim 2019 **Level IV PK**).

The use of IV propacetamol and IV paracetamol has been associated with hypotension (with variable definitions: systolic vs MAP change – absolute value or 15-20% decrease) in mostly critically ill (often cardiac) patients (14/19 studies) (Maxwell 2019 **Level IV SR**, 5 RCTs & 14 studies, n=3,470). Hypotension may be more prevalent with IV vs NG paracetamol in critically ill patients (Kelly 2016 **Level II**, n=50, JS 3). Clinically significant hypotension appears to be an issue when patients have cardiovascular compromise prior to administration; importantly regular qid dosing with IV paracetamol exposes the patient to ≈0.23 mg/kg/d mannitol (with its diuretic and secondary hypotensive effect) (Chiam 2015 **NR**). Within the above SR, IV paracetamol (with mannitol excipient) vs mannitol vs placebo reduced MAP by only 1.8 mmHg in healthy adult volunteers (Chiam 2016 **Level II**, n=24, JS 5).

Due to the good bioavailability and tolerability of oral paracetamol, the use of the IV form should be limited to clinical circumstances where use of the enteral route is not appropriate.

There does not appear to be a clinically significant difference in efficacy between IV and oral paracetamol (see Section 5.1.1 above).

5.2.2 | Nonselective NSAIDs and coxibs

Compared with PO NSAIDs, there are only a relatively limited number of nsNSAIDs or coxibs available for IV injection at present, although this number is growing.

IV/IM Ketorolac is an effective adjuvant of multimodal analgesia with more beneficial effect of 60 mg than 30 mg and a greater opioid-sparing effect with IM than IV administration (MD -2.13 mg; 95%CI -4.1 to -0.21 mg) (De Oliveira 2012 **Level I** [PRISMA] 13 RCTs, n=782).

IV Ibuprofen in doses of 400 and 800 mg every 6 h postoperatively as an adjuvant to IV PCA morphine resulted in improved analgesia, but only the 800 mg dose showed an opioid-sparing

effect (Southworth 2009 **Level II**, n=406, JS 3). IV Ibuprofen 800 mg has also shown efficacy after orthopaedic surgery (Singla 2010a **Level II**, n=185, JS 3), abdominal hysterectomy (Kroll 2011 **Level II**, n=319, JS 3) and laparoscopic cholecystectomy (Ekinci 2019, **Level II**, n=90, JS 4). IV ibuprofen at 800 mg was more effective at relieving renal colic pain at 15, 30 and 60 min than IV ketorolac 30 mg (Forouzanfar 2019 **Level II**, n=240, JS 4).

In single doses as the sole analgesic agent, the COX-2 selective IV/IM parecoxib has been shown to be effective in a dose-dependent way (Lloyd 2009 **Level I** [Cochrane] 7 RCTs, n=1,446); $NNT_{50\%}$ vs placebo are for 10 mg 3.1 (95%CI 2.4 to 4.5), 20 mg 2.4 (95%CI 2.1 to 2.8) and 40 mg 1.8 (95%CI 1.5 to 2.3).

A single dose of IV diclofenac is effective for postoperative pain after a variety of surgeries (McNicol 2018 **Level I** [Cochrane], 8 studies, n=1,756).

IV dexketoprofen 50 mg vs IV diclofenac 75 mg resulted in less IV PCA morphine usage after laparoscopic cholecystectomy over 24 h (18 vs 46mg) (Anil 2016, **Level II**, n=60, JS 2).

IV meloxicam used as a rescue for moderate-severe pain after bunionectomy reduced pain intensity and need for further rescue opioids vs placebo (Pollak 2018, **Level II**, n=201, JS=5). IV meloxicam 15, 30 and 60 mg had faster onset of and then longer-lasting analgesia vs a single dose of PO ibuprofen 400 mg after dental impaction surgery but IV meloxicam 15mg did not provide superior analgesia to PO ibuprofen 400 mg from 2 to 8 h post administration (Christensen 2018 **Level II**, n=230, JS 5).

Both IV and IM administration of lornoxicam were similarly effective for the treatment of acute renal colic pain (with no placebo comparator) (Soylu 2019, **Level II**, n=51, JS 2).

IV flurbiprofen (given 15 min before mastectomy and 6 h post) reduced pain at 2 h but not at later points of time, nor did it reduce overall opioid consumption. The number of patients with chronic postsurgical pain at 6 mth was reduced vs placebo (3.3 vs 26.7%) (Sun 2013, **Level II**, n=60, JS 5).

IV indomethacin is only approved for use in closure of a patent ductus arteriosus in neonates and there are no recent trials in humans for acute pain.

In most cases, the route of administration does not seem to alter efficacy. IV NSAIDs or COX-2 selective inhibitors are more expensive than oral or rectal NSAIDs, although their efficacy and likelihood of adverse effects is similar (Tramer 1998 **Level I**, 26 RCTs, n=2,225). For renal colic, the onset of action of NSAIDs is faster when administered IV vs IM, PO or PR. A comparison of rectal diclofenac and IV parecoxib showed no difference in pain relief, adverse effects or rescue analgesic requirements after laparoscopic sterilisation (Ng 2008 **Level II**, n=55, JS 5). Efficacy and times to onset of analgesia are similar with IV and IM parecoxib after oral surgery (Daniels 2001 **Level II**, n=304, JS 5).

5.2.3 | Conventional and atypical opioids

5.2.3.1 | Intermittent intravenous bolus doses

Titration of opioids for severe acute pain is best achieved using intermittent IV bolus doses as it allows more rapid titration of effect and avoids the uncertainty of medicine absorption by other routes. The optimal doses and dose intervals for this technique have not yet been established.

In a postoperative care unit, bolus doses of morphine 2 mg or 3 mg, given at 5 min intervals prn and with no limitation on the number of bolus doses administered, was more effective and resulted in no greater incidence of adverse effects than the same doses given at 10 min intervals or when a maximum of five doses only was allowed (Aubrun 2001 **Level III-3**, n=1,600; Aubrun 2012 **NR**).

In prehospital care, an initial dose of IV morphine 0.1 mg/kg was more effective than 0.05 mg/kg followed by half the initial dose at 5 min prn (VAS ≤30/100: 40% vs 17% at 10 min) (Bounes 2008 **Level II**, n=106, JS 5). In a comparison of IV fentanyl and morphine bolus doses every 5 min as needed for prehospital analgesia over a period of just 30 min, no difference was found in pain relief or incidence of adverse effects (Galinski 2005 **Level II**, n=54, JS 5).

A single dose of IV morphine 10 mg vs IV paracetamol 1,000 mg in moderate to severe traumatic limb pain had a similar analgesic effect with significantly more adverse effects in the morphine arm; approximately one-third of patients in each group required rescue analgesia of titrated IV morphine (Craig 2012 **Level II**, n=55, JS 4).

Titration of IV bolus doses of an opioid is frequently accomplished using a treatment algorithm to guide management, which includes age-based bolus doses of opioid given at 3- or 5-min intervals prn (Macintyre 2015 **NR**).

Approximately one-third of patients given a 1 mg single bolus dose of hydromorphone (followed by another dose at 15 min if needed) desaturated below 95% (Chang 2009 **Level IV**, n=269). As a standardised therapy, a single 2 mg dose of IV hydromorphone in adults <65 y old resulted in more patients (11.6%; 95%CI 1.8% to 21.1%) not requiring further pain relief after 30 min vs standard care (any IV opioid in any dose) (Chang 2013 **Level II**, n=350, JS 4). Adverse effects of pruritus and nausea were more common in the hydromorphone group, who received double the morphine equivalent dose; however, all patients received oxygen via nasal prongs to prevent desaturation. Comparing the 2 mg hydromorphone bolus to a "*1+1*" titration protocol, both showed similar efficacy and safety with an opioid-sparing effect noted in the titration group, where 42.3% required only the first bolus (Chang 2013 **Level II**, n=350, JS 4).

For acute traumatic pain in an ED setting, sufentanil given as an IV bolus of 0.15 mcg/kg followed by 0.075 mcg/kg every 3 min was not more effective than IV morphine 0.15 mg/kg followed by 0.075 mg/kg and less effective at 6 h (Bounes 2010 **Level II**, n=108, JS 5).

IV tramadol was found to be more effective than the same dose given PO after dental surgery, however it was recognised that the difference in bioavailability of a single dose of tramadol may be up to 30% (Ong 2005 **Level II**, n=72, JS 5). Large IV bolus doses of tramadol can result in a high incidence of nausea and vomiting. This effect can be reduced by slowing delivery of the medicine or, in the surgical setting, by giving it before the patient emerges from general anaesthesia (Pang 2000 **Level II**, n=60, JS 5).

Comparing intermittent oxycodone with other opioids reveals oxycodone is more effective than fentanyl (5 of 6 RCTs) and sufentanil (1 of 3 RCTs) and equivalent to morphine (Raff 2019 **Level I**, 6 RCTs, n=466 [vs fentanyl]; 3 RCTs, n=287 [vs sufentanil]; 2 RCTs, n=135 [vs morphine]). There was more nausea (3 of 6 RCTs) and vomiting (1 of 6 RCTs) reported in individual RCTs with oxycodone vs fentanyl.

5.2.3.2 | Continuous infusions

A continuous infusion of opioids results in constant blood levels after approximately four to five half-lives of the opioid used. The aim of an infusion is to avoid the problems associated with the peaks and troughs of intermittent administration techniques. However, the variation in patient response, the changing intensity of acute pain with time and the delay between any alteration of the infusion rate and its subsequent effect, may result in inadequate treatment of incident pain or delayed onset of adverse effects, such as respiratory depression. Very close monitoring is therefore essential with continuous infusions of opioids.

Compared with PCA, continuous IV opioid infusions alone in a general ward setting resulted in a five-fold increase in the incidence of respiratory depression (Schug 1993 **Level IV**, n=3,016).

Furthermore, morphine infusion 0.5 mg/h vs PCA alone after abdominal hysterectomy resulted in higher opioid requirements, pain intensity and adverse effects including POV and dizziness (Chen 2011 **Level II**, n=60, JS 4).

PCA with a continuous background infusion increases the risk of respiratory events in comparison to PCA alone in adults only (OR 10.2; 95%CI 3 to 35) (George 2010 **Level I**, 12 RCTs [adults], n=674). Despite these safety concerns, PCA with a continuous background infusion of low-dose oxycodone (0.01 mg/kg/h) vs PCA alone reduced VAS at 1, 6 and 24 h after laparoscopic radical cervical surgery without altering satisfaction, PONV or FAS (Zhu 2019 **Level II,** n=90. JS 4).

KEY MESSAGES

1. Intravenous paracetamol is more effective in reducing pain, opioid consumption and PONV when given prior to versus after surgical incision (**U**) (**Level I** [PRISMA]).
2. The onset of analgesia is faster when NSAIDs are given intravenously for the treatment of renal colic (**U**) (**Level I**).
3. Continuous intravenous infusion of opioids in the general-ward setting is associated with an increased risk of respiratory depression compared with other methods of parenteral opioid administration (**U**) (**Level IV**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Titration of opioids for severe acute pain is best achieved using intermittent intravenous bolus doses as it allows more rapid titration of effect and avoids the uncertainty of medicine absorption by other routes (**U**).

5.3 | Intramuscular and subcutaneous routes

IM and SC injections of analgesic agents (usually opioids) are still commonly employed for the treatment of moderate or severe pain. Absorption may be impaired in conditions of poor perfusion (eg in hypovolaemia, shock, hypothermia or immobility), leading to inadequate early analgesia and late absorption of the medication depot when perfusion is restored.

5.3.1 | Nonselective NSAIDs and coxibs

Compared to oral NSAIDs there are only a relatively limited number of NSAIDs or COX-2 selective inhibitors available for IM injection at present and fewer still where Level I evidence for individual efficacy is available; IM ketorolac (Lloyd 2009 **Level I** [Cochrane], 7 RCTs, n=1,446) and IM parecoxib are effective analgesic agents (De Oliveira 2012 **Level I** [PRISMA], 13 RCTs, n=782).

IM diclofenac administration has been associated with rare soft tissue necrosis, particularly in obese patients where the needle may not be long enough to reach the muscle (Dadaci 2015 **Level IV**, n=17 [mean BMI 42]).

5.3.2 | Conventional and atypical opioids

5.3.2.1 | Intramuscular

IM injection of opioids has been the traditional mainstay of postoperative pain management despite the fact that surveys have repeatedly shown that pain relief with prn IM opioids is frequently inadequate. Although IM opioids are often perceived to be safer than opioids given by other parenteral routes, the incidence of respiratory depression reported in a review ranged from 0.8% (0.2 to 2.5) to 37.0% (22.6 to 45.9) using respiratory rate and oxygen saturation, respectively, as indicators (Cashman 2004 **Level IV SR**, 165 studies, n≈20,000). For comparisons with PCA and epidural analgesia see Chapter 6; for comments on respiratory rate as an unreliable indicator of respiratory depression see Section 4.3.1.5.

Single doses of IM morphine 10 mg (McQuay 1999 **Level I**, 15 RCTs, n=1,046) and IM pethidine (meperidine) 100 mg (Smith 2000 **Level I**, 8 RCTs, n=364) have been shown to be effective in the initial treatment of moderate to severe postoperative pain.

The use of an algorithm allowing administration of IM morphine or pethidine hourly prn and requiring frequent assessments of pain and sedation, led to significant improvements in pain relief vs longer dose interval prn regimens (Gould 1992, **Level III-3**, n=235).

The quality of pain relief is lower with intermittent IM regimens vs IV PCA (McNicol 2015 **Level I** [Cochrane], 49 RCTs, n=3,412).

5.3.2.2 | Subcutaneous

The placement of SC plastic cannulae or 'butterfly' needles allows the use of intermittent injections without repeated skin punctures. In healthy volunteers, median time to reach maximum serum concentration (T_{max}) after SC injection of morphine was 15 min (Stuart-Harris 2000 **PK**). In elderly adults, mean T_{max} after a single SC injection of morphine was 15.9 min and the rate of absorption and the variability in the rate of absorption were similar to those reported after IM injection (Semple 1997 **Level IV PK**, n=22). In patients given a second and same dose of SC morphine 5 h after the first, it was shown that there can also be significant within-patient variations in absorption (Upton 2006 **PK**). The absorption rate of SC fentanyl was found to be similar to that of SC morphine with a significantly longer terminal half-life for fentanyl (10 h vs

2.1 h) (Capper 2010 **Level IV PK**). For SC oxycodone, peak venous concentrations were seen after 22.10 min (±18.0) in healthy controls however, despite similar onset, peak plasma concentrations were markedly reduced in critically ill ICU patients vs these healthy volunteers (Krishnamurthy 2012 **Level IV EH PK**). Similarly, SC tramadol in healthy volunteers had a time to peak venous concentration of 20.6 min (±18.8), however, unlike oxycodone, plasma concentrations were not reduced in critically ill patients vs healthy controls (Dooney 2014 **Level IV EH PK**).

In children, there was no difference in rate of onset, analgesic effect and adverse effects with use of morphine SC vs morphine IM and there was a significantly higher patient preference for the SC route (Cooper 1996 **Level II**, n=55, JS 4; Lamacraft 1997 **Level IV**, n=220 [paediatric]). Also, IM and IV administration of morphine (along with IN fentanyl) were found to be equally effective with no significant differences in FLACC scores for postoperative pain in children (Hippard 2012 **Level II**, n=171, JS 5). A comparison of IM and SC morphine in patients after Caesarean section reported no significant differences in adverse effects, patient satisfaction or pain relief at rest, but lower pain scores after SC administration at 12, 16 and 20 h after surgery (Safavi 2007 **Level II**, n=60, JS 3).

A comparison of the same dose of morphine given as either a single SC or IV injection, showed that use of the IV route resulted in more rapid onset of analgesia (5 min IV vs 20 min SC) and better pain relief between 5 and 25 min after injection but also led to higher sedation scores up to 30 min after injection and higher $PaCO_2$ (Tveita 2008 **Level II**, n=40, JS 5). However, a comparison of intermittent IV and SC doses of hydromorphone (the doses adjusted in a similar manner according to the patients' pain scores and given at intervals of no less than 3 h) showed no differences in pain relief or adverse effects over a 48 h period after surgery; pain relief was the same but the incidence of pruritus lower vs PCA hydromorphone (Bell 2007 **Level II**, n=130, JS 3).

Continuous infusions of opioids via the SC route were as effective as continuous IV infusions (Semple 1996 **Level II**, n=30, JS 2).

Treatment algorithms for intermittent SC morphine, oxycodone and fentanyl using age-based dosing are published (Macintyre 2015 **GL**).

KEY MESSAGE

1. Intermittent subcutaneous morphine injections are as effective as intramuscular injections and have better patient acceptance (**U**) (**Level II**).

5.4 | Transdermal route

Not all medications applied topically have a local, peripheral action. The term 'transdermal' will be used to describe medications that, while applied to the skin, have predominantly central effects that are the result of systemic absorption of the medicine. The term 'topical' will be used in the discussion of medications – primarily NSAIDs – that are applied topically (including to skin) but have a predominantly peripheral effect. See Sections 5.4.2 and 5.5 below.

5.4.1 | Opioids

The stratum corneum of the epidermis forms a major barrier to the entry of medications. However, medications such fentanyl (Sathyan 2005 **PK**) and buprenorphine (Skaer 2006 **NR**) are available as TD preparations. The analgesic effects are a result of systemic effects rather than local peripheral opioid analgesia (Worrich 2007 **Level IV EH**, n=12).

5.4.1.1 | Transdermal fentanyl

TD fentanyl is commonly used in the management of cancer and chronic pain. Due to the formation of a significant intradermal reservoir, onset and offset times of this preparation are slow and this makes short-term titration impossible. The time to first analgesic effect is generally between 12 and 24 h after initial patch application and after the patch is removed, serum fentanyl concentrations decline with a mean terminal half-life of 17 h (Lotsch 2013 **NR**).

TD fentanyl patches are currently specifically contraindicated for the management of acute or postoperative pain in many countries and for use in opioid naïve patients (FDA 2019a **GL**; MIMS 2019 **GL**; emc 2014 **GL**).

Nevertheless, TD fentanyl patches have been trialled in the management of postoperative pain. For example after THA (Minville 2008 **Level II**, n=30, JS 2), TKA (Sathitkarnmanee 2014 **Level II**, n=40, JS 5; Abrisham 2014 **Level II**, n=40, JS 5), foot surgery (Merivirta 2015 **Level II**, n = 60, JS 5) and hysterectomy (Sandler 1994 **Level II**, n=120, JS 4), preoperative use reduced postoperative pain scores and supplementary opioid or other analgesic requirements. However, the wide variability of clinical effect (Peng 1999 **NR**) and the high incidence of respiratory depression that can occur in the postoperative setting (Bulow 1995 **Level II**, n=24 [then terminated for safety concerns], JS 4; Sandler 1994 **Level II**, n=120 [9 patients withdrawn due to severe respiratory compromise], JS 4) make TD fentanyl preparations unsuitable for acute pain management. In line with these concerns and reported fatal outcomes with perioperative use, guidelines advise against the use of transdermal fentanyl in acute pain management (ANZCA 2018 **GL**). There are concerns that studies in this indication are still undertaken and published (Nair 2017 **NR**).

Transdermal fentanyl by an iontophoretic PCA device for the management of acute pain is also available. See Section 6.5.5.

5.4.1.2 | Transdermal buprenorphine

TD buprenorphine patches are available for the management of chronic and cancer pain (Plosker 2011 **NR**). After application of the patch, steady state is achieved by 3 d; after removal of the patch, buprenorphine concentrations decrease with a terminal half-life of 12 h (range 10 to 24 h). High doses of buprenorphine patch (above 40 mcg/hr) may cause QT wave prolongation that is reversible with mu-opioid antagonists; clinical significance of this is unclear (Merivirta 2015 **Level III-1**, n=110). As with other chronic preoperative opioid use, patients on TD buprenorphine

preoperatively and continued through the perioperative period show higher opioid requirements and report worse pain than opioid-naïve controls (Martin 2019 **Level-III 2**, n=19).

TD buprenorphine showed a dose-dependent analgesic effect with no serious adverse effects in gynaecological postoperative patients (Setti 2012 **Level II**, n=47, JS 4). Use of TD buprenorphine for acute pain management in spinal surgery was noninferior to oral tramadol (Kim 2017 **Level II**, n=48, JS 3) and superior to placebo (Niyogi 2017 **Level II**, n=70, JS 5). TD buprenorphine in abdominal surgery was associated with superior analgesia but comparable adverse effect profile to placebo (Kumar 2016 **Level II**, n=90, JS 5). After surgical repair of hip fractures, TD buprenorphine 10 mcg/h vs PO tramadol 50 mg tds provided better analgesia from 24 h to POD 7 with lower rescue requirements and less PONV and higher patient satisfaction (Desai 2017 **Level II**, n=5, JS 3). After hallux valgus repair, TD buprenorphine 10 mcg/h provided superior analgesia vs celecoxib 400 mg/d and comparable analgesia to IV flurbiprofen 50 mg twice daily with highest patient satisfaction (Xu 2018 **Level II**, n=90, JS 3).

Inherent difficulty in titrating the dose according to changing analgesic requirement should be considered when using TD buprenorphine for acute pain management.

5.4.2 | Other medicines

There is no basis to recommend routine use of TD nicotine patches for acute pain management in view of no demonstrable effect on analgesia (Matthews 2016 **Level I** [Cochrane], 9 RCTs, n=666).

TD administration of ketamine as a patch delivering 25 mg over 24 h reduced rescue analgesic consumption after gynaecological surgery (Azevedo 2000 **Level II**, n=52, JS 4).

TD melatonin 7 mg patch for perioperative pain management in lumbar laminectomy was superior to placebo in analgesia and reduced supplementary analgesia consumption, but was associated with significant sedation (Esmat 2016 **Level II**, n = 75, JS 5).

TD diclofenac patches have been applied in nonsurgical settings for systemic (non-topical) analgesia. They have been trialled for acute pain management after dental surgery and 75 mg and 200 mg patches were comparable in effect to oral diclofenac 75 mg and 100 mg twice daily (Krishnan 2015 **Level II**, n = 40, JS 2; Diwan 2019 **Level III-1**, n=20, JS 2). Another study found TD diclofenac patch 100 mg applied preoperatively to be noninferior to IM diclofenac 75 mg at surgical cessation but with a longer duration of action (Perepa 2017 **Level III-1**, n=60, JS 2).

KEY MESSAGES

1. Transdermal buprenorphine reduces postoperative pain with a low rate of adverse effects (**N**) (**Level II**).
2. Transdermal fentanyl (except for iontophoretic patient-controlled transdermal devices) should not be used in the management of acute pain because of safety concerns and difficulties in short-term dose adjustments needed for titration (**S**) (**Level IV**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Transdermal fentanyl preparations should not be used in opioid-naïve patients or in acute pain settings because of safety concerns and, in most countries, the lack of regulatory approval for use in other than chronic pain in opioid-tolerant patients (**S**).

5.5 | Transmucosal routes

Medications administered by transmucosal routes (rectal, IN, SL, buccal and pulmonary) are rapidly absorbed directly into the systemic circulation, thus bypassing hepatic first-pass metabolism. The medications most commonly administered by transmucosal routes in acute pain management are the more lipid-soluble opioids.

5.5.1 | Rectal route

Rectal administration (PR) of medications is useful when other routes are unavailable. It results in uptake into the submucosal venous plexus of the rectum, which drains into the inferior, middle and superior rectal veins. Medication absorbed from the lower half of the rectum will pass into the inferior and middle rectal veins and then the inferior vena cava, bypassing the portal system. Any portion of the medicine absorbed into the superior rectal vein enters the portal system, subjecting it to hepatic first-pass metabolism.

Potential problems with the administration of medication by the rectal route relate to the variability of absorption, possible rectal irritation and cultural factors. Some suppositories should not be divided as the medicine may not be evenly distributed in the preparation. Contraindications to the use of this route include pre-existing rectal lesions, recent colorectal surgery, severe thrombocytopaenia and immune suppression. Whether the medication is administered to a patient who is awake or under anaesthesia, it is important to obtain prior consent from the patient or guardian.

5.5.1.1 | Paracetamol

Paracetamol is effective when given by the rectal route (Romsing 2002 **Level I**, 8 RCTs, n=640), although absorption is slower and less predictable than after oral administration with bioavailability between 24 and 98% (Oscier 2009 **NR**). In children, it is also less effective than the same dose administered by the oral route (Anderson 1996 **Level II**, n=100, JS 4; Anderson 1999 **Level IV**, n=120). However, in children aged 3 to 36 mth, there were no differences in T_{max}, C_{max} and total medicine exposure between rectal and oral administration, possibly due to slower gastric emptying in this age group (Walson 2013 **Level II**, n=30, JS 2).

Doses of 1 g PR after cardiac surgery (Holmer Pettersson 2006 **Level II**, n=48, JS 2), hysterectomy (Kvalsvik 2003 **Level II**, n=60, JS 4) and 2 g PR for laparoscopic gynaecological surgery (Hahn 2000 **Level IV**, n=23) resulted in subtherapeutic plasma concentrations, although these may increase to within the therapeutic range after repeat administration (Holmer Pettersson 2006 **Level II**, n=48, JS 2). When available, the oral route is therefore preferable.

Higher doses may be more effective. Plasma concentrations in the therapeutic range have been reported in adults after PR doses of 40 mg/kg but not 20 mg/kg (Beck 2000 **Level IV**, n=65) and sustained therapeutic levels followed the PR use of 35 mg/kg and 45 mg/kg, but not 15 mg/kg and 25 mg/kg (Stocker 2001 **Level IV PK**, n=10).

In children, initial PR doses of 40 mg/kg followed by 20 mg/kg also provided therapeutic plasma concentrations without evidence of accumulation (Birmingham 2001 **Level IV PK**, n=16). In children after ophthalmic surgery, 20 and 40 mg/kg PR were equally effective and superior to placebo (Gandhi 2012 **Level II**, n=135, JS 4). PR paracetamol 30 mg/kg provided equivalent analgesia postoperatively vs peritonsillar infiltration of bupivacaine (Dahi-Taleghani 2011 **Level III-1**, n=110). For inguinal herniorrhaphy in children, administration of PR paracetamol appeared to be as effective as IV paracetamol, both in postoperative analgesia and reduction in nausea and

vomiting (Khalili 2016 **Level II**, n=120, JS 3). However, addition of PR paracetamol to caudal epidural block did not result in a meaningful improvement vs caudal block alone for the same procedure (Nnaji 2017 **Level II**, n=87, JS 4).

5.5.1.2 | NSAIDs

Rectal administration of nsNSAIDs provides effective analgesia after a variety of surgical procedures (Tramer 1998 **Level I**, 26 RCTs, n=2,225). This continues to be supported by a number of subsequent studies (Karaman 2016 **Level II**, n=82, JS 5; Nadeem 2016 **Level II**, n=60, JS 3; Pazouki 2015 **Level III-1**, n=130). A study comparing PR diclofenac vs PR indomethacin for postepisiotomy pain found both to be similarly effective but diclofenac appeared to have a shorter duration of action (Rezaei 2014 **Level II**, n=90, JS 3).

Local effects such as rectal irritation and diarrhoea have been reported following use of the rectal route but other commonly reported adverse effects such as nausea, vomiting, dizziness and indigestion are independent of the route of administration (Tramer 1998 **Level I**, 26 RCTs, n=2,225). Rectal NSAIDs may be particularly useful as a part of multimodal analgesia in cases where an enteral route cannot be established, such as immediately after upper GI surgery (Bameshki 2015 **Level II**, n=90, JS 2).

In comparison to PR paracetamol, PR NSAIDs were more efficacious (Nikooseresht 2016 **Level II**, n=102, JS 1; Ubale 2016 **Level II**, n=60, JS 2). The synergistic benefit of combining paracetamol with an NSAID was also confirmed for the rectal route. After abdominal hysterectomy, PR paracetamol/PR diclofenac vs PR diclofenac only or vs placebo resulted in superior analgesia and significantly reduced rescue opioid requirements (Samimi Sede 2014 **Level II**, n=90, JS 4). PR NSAIDs showed superior analgesic effect when combined with paracetamol in adults (Bakhsha 2016 **Level III-1**, n=90) and children (Yallapragada 2016 **Level II**, n=60, JS 2), and also with other analgesics such as pentazocine (Olateju 2016 **Level II**, n=116, JS 5).

To provide analgesia after gynaecological procedures, PR indomethacin was superior to placebo, but inferior to intrauterine lignocaine for hysteroscopy (Senturk 2016 **Level II**, n=206, JS 4), and conferred no advantage over placebo after endometrial biopsies (Kaya 2015 **Level II**, n=90, JS 2; Telli 2014 **Level II**, n=151, JS 4).

For inguinal herniorrhaphy in children, addition of PR diclofenac to caudal epidural block did not result in improved analgesia vs caudal block alone (Nnaji 2017, **Level II**, n=87, JS 4).

For periprocedural analgesia in US-guided prostate biopsy, PR diclofenac is superior to placebo (3 RCTs), but inferior to the gold standard of periprostatic nerve block (2 RCTs) (Lee 2014a **Level I**, 106 RCTs, n unspecified). Administration 45 to 60 min prior to procedure is recommended. While the same systematic review found some benefit in combining PR diclofenac with periprostatic block (2 RCTs), a subsequent RCT failed to find additional benefit with this approach vs periprostatic block alone (Ooi 2014 **Level II**, n=96, JS 4).

For acute renal colic in the Emergency Department (ED), PR indomethacin 100 mg provided analgesia slightly inferior to PR morphine 10 mg at 20 min but was equivalent afterwards (Zamanian 2016 **Level II**, n=158, JS 5) and was inferior to IM tramadol 50 mg, with significantly higher need for rescue analgesia (Shirazi 2015 **Level II**, n=120, JS 3).

5.5.1.3 | Opioids

In most instances, similar doses of rectal and oral opioids are administered, although there may be differences in bioavailability and the time to peak analgesic effect for the reasons outlined above; rectal opioids play primarily a role in cancer-pain management (Kestenbaum 2014 **NR**). Here, no differences in either pain relief or adverse effects were found in a comparison of oral and rectally administered tramadol (Mercadante 2005 **Level II**, n=60, JS 5). Analgesic effects of rectal

opioids in acute procedural pain settings have been demonstrated (Imani 2018 **Level II**, n=90, JS 2; Rahimi 2016 **Level II**, n=70, JS 4); advantages of this approach are unclear if oral or parenteral routes are available.

5.5.1.4 | Ketamine

Rectal ketamine is advantageous for the paediatric population, when parenteral access may not be feasible and a degree of sedation in addition to analgesia is desirable. PR ketamine 2 mg/kg provided comparable analgesia to IV ketamine 0.5 mg/kg when delivered intraoperatively during tonsillectomy in children (Yenigun 2015 **Level II**, n=120, JS 1). Higher doses of PR ketamine (4 mg/kg, 6 mg/kg and 8 mg/kg) were trialled in addition to 0.5 mg/kg midazolam for analgo-sedation for outpatient burns dressing changes in children, and it was noted that the higher dose of 8 mg/kg was associated with prolonged recovery time and adverse events (Grossmann 2019 **Level II**, n=90, JS 5); a dose of ketamine 6 mg/kg with midazolam 0.5 mg/kg appeared to provide the best balance between the degree of analgo-sedation and adverse effects.

5.5.2 | Intranasal route

A variety of different medications can be administered by the IN route, including analgesics. The human nasal mucosa contains medication-metabolising enzymes but the extent and clinical significance of human nasal first-pass metabolism is unknown (Dale 2002 **NR**). It is suggested that the volume of a dose of any medication given IN should not exceed 150 microL in order to avoid run-off into the pharynx (Dale 2002 **NR**). Absorption through the nasal mucosa depends on both the lipid solubility and degree of ionisation of the medication (Shelley 2008 **NR**).

5.5.2.1 | NSAIDs

IN ketorolac has also been shown to be effective vs placebo. After major surgery, ketorolac IN 31.5 mg (Singla 2010b **Level II**, n=321, JS 5) but not 10 mg IN resulted in significant opioid-sparing and better pain relief (Moodie 2008 **Level II**, n=127, JS 5). This was also found for IN 31.5 mg after oral surgery (Grant 2010 **Level II**, n=80, JS 5). For acute migraine, IN ketorolac 31.5mg was superior to placebo and at least as effective as IN sumatriptan 20 mg (Rao 2016 **Level II**, n=72, JS 5).

5.5.2.2 | Opioids

Single-dose pharmacokinetic data in healthy volunteers for a number of opioids administered by the IN route have been published (Dale 2002 **NR**; Grassin-Delyle 2012 **NR**). The mean bioavailabilities and T_{max} reported were fentanyl 71% and 5 min; sufentanil 78% and 10 min; alfentanil 65% and 9 min; butorphanol 71% and 49 min; oxycodone 46% and 25 min; and buprenorphine 48% and 30 min. An analysis of multiple trials for IN fentanyl showed a bioavailability of 89% with an onset of analgesia at 2–5 min (Lotsch 2013 **NR**). Hydromorphone, when given to volunteers in doses of 1 mg or 2 mg IN vs 2 mg IV, had median T_{max} after the 1 mg and 2 mg IN doses of 20 min and 25 min respectively and an overall bioavailability of only 55% (Coda 2003 **PK**).

Clinical data exist for the effectiveness of several opioids administered via the IN route. IN fentanyl must be provided in a sufficient concentration to deliver an analgesic dose in a volume that does not exceed the nasal capacity. It is an effective treatment for breakthrough pain in cancer patients (Zeppetella 2013 **Level I** [Cochrane] 15 RCTs [4 INF], n=1,699) and has similar analgesic efficacy to IV administration in the ED and prehospital settings (Hansen 2012 **Level I** [PRISMA], 3 RCTs, n=301). IN fentanyl spray vs oral transmucosal fentanyl, fentanyl buccal tablet and oral morphine for the treatment of breakthrough cancer pain provides the greatest and fastest

improvement (Vissers 2010 **Level I**, 6 RCTs, n=594) (see also Section 8.9.3.2). It provides also similar or better analgesia than other opioids or routes of administration in children without compromising safety (Mudd 2011 **Level IV SR**, 12 studies, n=1,743). Effectiveness of IN fentanyl for paediatric acute pain management is confirmed by two systematic reviews (Murphy 2014 **Level I** [Cochrane], 3 RCTs, n=313; Setlur 2018 **Level I** [PRISMA], 10 RCTs, n=5,945) (2 RCTs overlap) (see also Section 10.9.1.2). When IN fentanyl was used in the prehospital setting, there was no difference in effectiveness vs IV morphine (Rickard 2007 **Level II**, n=258, JS 3) and it was also effective for burns dressing changes (Nederveld 2017 **Level III-2**, n=64) (see Section 8.5.3.1). In paediatric sickle cell crisis, it was superior to placebo at 20 min, but not earlier or later (Fein 2017 **Level II**, n=49, JS 5). Adding IN fentanyl to nitrous oxide 70% for paediatric procedural sedation does not confer any advantage for short duration procedures (Seiler 2019 **Level II**, n=399, JS 5).

Two studies have examined the role of IN fentanyl delivered via postoperative nasal packing foam soaked in fentanyl solution after nasal passage operation (Kim 2018b **Level II**, n=152, JS 5) and nasal fracture repair (Kim 2019c **Level II**, n=65, JS 5). In both cases superior analgesia vs placebo lasting for up to 24 h was achieved without an increase in adverse events. The authors postulate a significant local analgesic effect in addition to systemic absorption.

Analgesic efficacy has also been shown for IN butorphanol (Wermeling 2005 **Level II**, n=60, JS 4; Abboud 1991 **Level II**, n=186, JS 5), IN pethidine (Striebel 1995 **Level II**, n=44, JS 2; Striebel 1993 **Level II**, n=60, JS 5), IN morphine (Stoker 2008 **Level II**, n=187, JS 5), IN hydromorphone (Wermeling 2010 **Level IV**, n=99) and IN sufentanil (Mathieu 2006 **Level II**, n=40, JS 4; Stephen 2012 **Level IV**, n=15; Steenblik 2012 **Level IV**, n=40).

Butorphanol (Abboud 1991 **Level II**, n=186, JS 5) and morphine (Christensen 2008 **Level II**, n=225, JS 5) had similar efficacy when given by IN or IV routes. IN butorphanol was similarly effective to IV butorphanol, and provided advantages of reduced postoperative cognitive decline vs IV fentanyl, when given to patients aged over 65 y for palate-pharyngoplasty (Yang 2015 **Level II**, n=260, JS 2). IN pethidine was more effective than SC injections of pethidine (Striebel 1995 **Level II**, n=44, JS 2). IN sufentanil has been trialled in the ED setting and was superior to placebo at 0.4 mcg/kg (Lemoel 2019 **Level II**, n=144, JS 5) and superior to IV morphine 0.1 mg/kg at 0.7 mcg/kg (Sin 2019 **Level II**, n=60, JS 5). In both studies adverse event profiles were minor and transient.

Patient-controlled IN analgesia (PCINA) using diamorphine (bolus doses of 0.5 mg) was less effective than PCA IV morphine (1 mg bolus doses) after joint replacement surgery (Ward 2002 **Level II**, n=52, JS 2) but provided better pain relief in doses of 0.1 mg/kg than 0.2 mg/kg IM morphine in children with fractures (Kendall 2001 **Level II**, n=404, JS 3). PCINA fentanyl (54 mcg 4 min lockout) provided better postoperative analgesia vs regular IM pethidine in women after Caesarean section (Fleet 2015 **Level II**, n=156, JS 3).

Adverse effects can be related to the medication itself or to the route of administration. Systemic effects appear to be no higher for IN administration than for other routes with equivalent efficacy; nasal irritation, congestion and bad taste have been reported (Grassin-Delyle 2012 **NR**; Dale 2002 **NR**).

Technical problems with pumps have been reported in up to 10% of cases and dispensing issues for techniques such as PCINA, which could allow ready and unauthorised access to the medications, have not been addressed (Dale 2002 **NR**).

5.5.2.3 | Ketamine

IN ketamine has been shown to provide relatively rapid onset of effective pain relief within 15 min (peak effect 30 min) with estimated bioavailability of 45% (Farnia 2017 **Level II**, n=53, JS 4); any adverse effects were mild and transient (Andolfatto 2019 **Level II**, n=120, JS 5; Christensen 2007 **Level II**, n=40, JS 4). Its use in the adult ED setting has been validated for orthopaedic trauma (Mohammadshahi 2018 **Level II**, n=91, JS 5), general trauma (Shimonovich 2016 **Level III-1**, n=90) and in the prehospital setting with demonstrated efficacy over placebo and analgesia comparable to IN/parenteral opioid (Andolfatto 2019 **Level II**, n=120, JS 5).

IN ketamine for acute headache was not found to be superior to metoclopramide/diphenhydramine (Benish 2019 **Level II**, n=53, JS 4). In adult renal colic, IV fentanyl was superior in both analgesic and adverse effect profiles to IN ketamine (Mozafari 2019 **Level II**, n=130, JS 5).

As well as a premedication in paediatric patients, IN ketamine has been studied for paediatric ED pain management and was similarly effective to the usual treatment of IN fentanyl, although associated with higher rate of mild transient adverse events (Frey 2019 **Level II**, n=90, JS 5; Reynolds 2017 **Level II**, n=82, JS 5; Graudins 2015 **Level II**, n=73, JS 5). See also Section 10.4.7.1.

IN ketamine for postoperative analgesia in paediatric tonsillectomy was similarly effective to IN fentanyl (Yenigun 2018 **Level III-1**, n=63). IN S(+)-ketamine combined with midazolam delivered on demand provided analgesia comparable to IV morphine PCA for patients who underwent spinal surgery (Riediger 2015 **Level II**, n=22, JS 4).

5.5.2.4 | Alpha-2 agonists

There is no data for use of clonidine via this route for analgesia in adults or children. The analgesic effect of IN dexmedetomidine has been shown in adult populations such as after hysterectomy (Wu 2016 **Level II**, n=120, JS 3) and endoscopic sinus surgery (Tang 2015 **Level II**, n=60, JS 5). IN dexmedetomidine is used in children for preoperative sedation, and may also confer additional analgesic benefits. IN dexmedetomidine 2 mcg/kg, but not 1 mcg/kg, was associated with clinically significant postoperative analgesia vs placebo (Li 2018b **Level II**, n=90, JS 5). IN dexmedetomidine had a similar analgesic effect to IN fentanyl after myringotomy when administered intraoperatively (Dewhirst 2014 **Level II**, n=100, JS 2). IN dexmedetomidine provided persistently better analgosedation for IV cannulation (as evidenced by FLACC score) when given through a mucosal atomization device (MAD) vs IN administration of drops of solution (Xie 2017 **Level II**, n=106, JS 3). See also Section 10.4.8.

5.5.2.5 | Others

IN lignocaine has shown poor efficacy in the treatment of acute headaches with significant adverse effects vs placebo (Dagenais 2018 **Level I**, 6 RCTs, n unspecified).

While IN nicotine may have a small analgesic effect, this has been inconsistently demonstrated and is associated with significant increase in PONV (Matthews 2016 **Level I** [Cochrane], 9 RCTs, n=666).

IN desmopressin relieved subacute pain after orthopaedic surgery for up to 24 h (Yang 2019 **Level II**, n=653, JS 3).

5.5.3 | Sublingual and buccal routes

When analgesic medicines are administered by the SL or buccal routes, their efficacy will in part depend on the proportion of medication swallowed.

5.5.3.1 | Opioids

A number of different SL fentanyl preparations are currently on the market world-wide; these include oral transmucosal fentanyl citrate (OTFC), fentanyl buccal tablets (FBT), SL fentanyl citrate orally disintegrating tablet (ODT) and fentanyl buccal soluble film (FBSF); in addition, buccal or SL sprays and a wafer are under development (Schug 2017 **NR**; Paech 2012 **NR**).

The only registered indication of these preparations (commonly called 'Transmucosal Immediate-Release Fentanyl (TIRF) medicines') in all countries is the treatment of break-through pain in opioid-tolerant cancer patients. SL and buccal fentanyl are effective treatments for breakthrough pain in cancer patients vs placebo, oral or IV opioid (Zeppetella 2013 **Level I** [Cochrane], 15 RCTs, n=1,699). In this indication, OTFC, FBT and ODT provide more efficacious analgesia than oral morphine (Jandhyala 2013 **Level I**, 5 RCTs, n=415) (5 RCTs overlap). However, as outlined above, IN fentanyl was superior to OTFC and FBT here (Vissers 2010 **Level I**, 6 RCTs, n=594) (5 & 6 RCTs overlap). See also Section 8.9.4.

In many countries, regulatory authorities have specifically noted that SL preparations must not be used in opioid-naïve patients or in the management of acute and postoperative pain: OTFC has been the suspected primary cause of death in 226 USA fatalities between 2004 and 2011 (Paech 2012 **NR**). As a consequence, warnings regarding the use of all TIRF formulations have been issued (FDA 2019b **GL**) and specifically for OTFC (MIMS 2019 **GL**; emc 2014 **GL**).

Oral transmucosal fentanyl citrate

OTFC incorporates fentanyl into a flavoured solid lozenge on a stick and is available in a range of doses from 200 to 1,600 mcg. Overall, the bioavailability of OTFC is about 50% vs IV fentanyl, with C_{max} achieved in 23 min (Lotsch 2013 **NR**); the time to onset of analgesia is about 4.2 min. The relative potency vs IV morphine is 1:8 to 1:14 (200 mcg OTFC≈2 mg IV morphine) (Lichtor 1999 **Level II**, n=133, JS 5).

Only a few studies have investigated the postoperative use of OTFC. It was found to be an effective analgesic after orthopaedic surgery vs placebo (Ashburn 1993 **Level II**, n=38, JS 5), abdominal surgery vs IV morphine (Lichtor 1999 **Level II**, n=133, JS 5), retinal photocoagulation vs placebo (Hillier 2009 **Level II**, n=35, JS 5) and during burns wound care in paediatric patients vs PO opioids (Sharar 2002 **Level II**, n=22, JS 3; Sharar 1998 **Level II**, n=14, JS 3). Pain relief at 15 min in children with lower extremity injuries was the same with IV bolus doses of morphine and OTFC, but lower with OTFC after that until the end of the 75-min study period (Mahar 2007 **Level II**, n=87, JS 3). However, because of the risk of achieving high peak plasma levels with unsupervised administration, the limited data available, and the specific lack of approval for use in opioid-naïve patients, OTFC cannot be recommended for the management of acute pain.

Fentanyl buccal tablets

FBTs use an effervescent medicine delivery technology that enables more rapid absorption and delivers a larger proportion of the fentanyl dose vs OTFC (Grape 2010 **NR**); bioavailability is 65% with time to onset of effect 10 min (Lotsch 2013 **NR**). FBTs are effective in opioid-tolerant cancer patients for breakthrough pain (Zeppetella 2013 **Level I** [Cochrane] 15 RCTs [2 FBT], n=1,699; Jandhyala 2013 **Level I**, 5 RCTs, n=415; Vissers 2010 **Level I**, 6 RCTs, n=594) (full overlap between all three SRs). Although only indicated for this usage, FBTs have been studied in the ED. Here, a 100 mcg FBT had faster onset of analgesia (10 vs 35 min) than an oxycodone 5 mg/paracetamol 325 mg

combination tablet, with no other advantages (Shear 2010 **Level II**, n=60, JS 4). FBT 200 mcg was noninferior to oxycodone 10 mg/paracetamol 650 mg in an ED setting, but again without obvious advantage in terms of onset, efficacy or adverse effect profile (Arthur 2015 **Level II**, n=50, JS 2). FBT was also trialled for treatment of sickle cell crisis (De Franceschi 2016 **Level III-2**). Use of FBT for non-cancer pain in opioid-naïve patients cannot be recommend given significant safety concerns.

Sublingual fentanyl citrate orally disintegrating tablets

SL fentanyl citrate ODTs consist of a mixture of carrier particles coated with fentanyl and a mucoadhesive agent and are left under the tongue to dissolve, leading to rapid fentanyl absorption (Paech 2012 **NR**). This leads to a bioavailability of around 70% and a time to onset of effect of 15 min (Lotsch 2013 **NR**). They are effective in opioid-tolerant cancer patients for breakthrough pain (Zeppetella 2013 **Level I** [Cochrane] 15 RCTs [2 ODT], n=1,699) and one subsequent RCT (Shimoyama 2015 **Level II**, n=37, JS 3). They have also been used with effect in breakthrough noncancer pain (Guitart 2013 **Level IV**, n=182).

Fentanyl buccal soluble film

FBSF consists of a small soluble disc-shaped film containing fentanyl in doses of 200–1,200 mcg, proportional to the film surface area (Grape 2010 **NR**); bioavailability is 71% and time to onset of effect 15 min (Lotsch 2013 **NR**). FBSF is effective in opioid-tolerant cancer patients for breakthrough pain (Zeppetella 2013 **Level I** [Cochrane] 15 RCTs [1 FBSF], n=1,699).

Other transmucosal fentanyl preparations

Fentanyl buccal spray has a bioavailability of 76% and a time to onset of effect of 5 min (Lotsch 2013 **NR**). It is effective in opioid-tolerant cancer patients for breakthrough pain (Zeppetella 2013 **Level I** [Cochrane], 15 RCTs [1 SL spray], n=1,699). Fentanyl SL wafers showed a bioavailability of 79% (Lim 2012 **PK**).

Sublingual buprenorphine

SL buprenorphine, given as a tablet, has an overall bioavailability of 30–50% and a long duration of action (mean half-life 28 h) (Mendelson 1997 **NR**; Kuhlman 1996 **NR**). SL buprenorphine 0.4 mg was found to be as effective as 10 mg morphine IM after abdominal surgery (Cuschieri 1984 **Level II**, n=89, JS 2) and 75 mg pethidine IM after gynaecological surgery (Moa 1990 **Level II**, n=96, JS 4). For adults with acute fractures in the ED, SL buprenorphine 0.4mg is as effective and safe as IV morphine 5 mg (Jalili 2012 **Level II**, n=49, JS 4). A much higher dose of SL buprenorphine 2 mg for renal colic achieved comparable analgesia and adverse event to IV morphine 0.1 mg/kg (Payandemehr 2014 **Level II**, n=69, JS 5).

First pass metabolism of buprenorphine is dependent on cytochrome P450-3A4. Concurrent administration of enzyme inhibitors such as voriconazole more than posaconazole significantly elevated plasma concentrations after SL buprenorphine in healthy volunteers (Fihlman 2016 **Level II PK**, n=12, JS 3). Similarly, co-administration of rifampicin, an enzyme inducer, reduced plasma concentration of buprenorphine after SL administration by up to 25%, but had no effect when buprenorphine was given IV (Hagelberg 2016 **Level III-2 PK**, n=12).

SL buprenorphine is at least as effective as parenteral morphine for treatment of acute pain with a comparable safety profile (Vlok 2019 **Level I** [PRISMA], 9 RCTs, n=826).

Sublingual sufentanil

Sufentanil is a lipophilic drug which rapidly crosses the blood-brain barrier ($t_{1/2keo}$ 6 min), resulting in a faster onset of action than morphine (Melson 2014 **NR**). Bioavailability of SL sufentanil is estimated at 60%; and vs IV administration, SL sufentanil has a blunted peak and prolonged plasma half-life (Ringold 2015 **NR**). A sublingual sufentanil tablet system (SSTS) has been developed commercially and incorporates a hand-held computerised dispenser which is activated by a

radiofrequency ID tag linked to an individual patient, and dispenses SL sufentanil 15 to 30 mcg tablets in a patient-controlled manner with a 20 min lockout (Frampton 2016 **NR**). See Section 6.5.3.

SSTS has been trialled in both postsurgical and other acute pain settings. Compared to IV morphine PCA for analgesia after major abdominal or TKA/THA surgeries, SSTS 15 mcg provided analgesia that was noninferior with similar rate of adverse effects and superior satisfaction ratings from patients and nursing staff (Melson 2014 **Level II**, n=357, JS 2). Specifically post TKA/THA, SSTS 15 mcg was superior to placebo but associated with a higher rate of nausea and vomiting (Jove 2015 **Level II**, n=419, JS 5). While for open abdominal surgery, the analgesia from SSTS was superior to placebo, with similar adverse events profiles for SSTS 15 mcg (Ringold 2015 **Level II**, n=172, JS 5) and SSTS 30 mcg, and rapid onset of reported analgesic effect within 15 min of administration (Minkowitz 2017 **Level II**, n=161, JS 5). SSTS 30 mcg was also trialled for acute pain management in the ED setting (Miner 2018 **Level III-3**, n=76).

5.5.3.2 | Ketamine

A pharmacokinetic study in healthy volunteers calculated the bioavailability of oral ketamine as 20%, SL 30% and IN 45%: the pharmacodynamic effects of the active metabolite norketamine were thought to be of potential significance (Yanagihara 2003 **PK**). The bioavailability of a 25 mg ketamine lozenge was 24% when given by both SL and oral routes; peak plasma levels were seen at 30 min and 120 min respectively and terminal half-lives were similar at around 5 h (Chong 2009 **PK**). For both routes, norketamine concentrations exceeded the concentrations of ketamine and, given its pharmacological activity profile, norketamine is therefore likely to be a major contributor to the overall analgesic effect. A wafer preparation of ketamine showed an oral bioavailability of 29% (Rolan 2014 **PK**).

5.5.3.3 | Others

Sublingual nsNSAIDs have been used in a variety of acute pain settings. One study found SL piroxicam to be noninferior to IM diclofenac for renal colic (KandaSwamy 2015 **Level II**, n=100, JS 5), and another found SL ketoprofen to have similar efficacy to oral naproxen for acute lower back pain (Plapler 2016 **Level II**, n=83, JS 3). A novel formulation of buccal paracetamol 125 mg was noted to provide analgesia similar to IV paracetamol 1 g for limb trauma in ED (Pickering 2015 **Level II**, n=40, JS 5). Advantages of above formulations over their oral equivalents are not clear.

Sublingual desmopressin vs IM ketorolac for renal colic was found to be similarly effective (Pricop 2016 **Level II**, n=249, JS 2).

5.5.4 | Pulmonary

5.5.4.1 | Opioids

Opioids are rapidly absorbed after nebulised inhalation, reflecting the high blood flow, surface area and permeability of the lungs.

Clinical data exist for the effectiveness of several opioids administered via the pulmonary route including morphine (Thipphawong 2003 **Level II**, n=89, JS 5; Dershwitz 2000 **Level IV PK**, n=15) and fentanyl (Miner 2007 **Level II**, n=41, JS 3; Worsley 1990 **Level II**, n=30, JS 3).

For post-traumatic thoracic pain, there was no difference in the pain relief obtained from nebulised morphine and PCA morphine (Fulda 2005 **Level II**, n=44, JS 4). Nebulised morphine 20 mg every 10 min vs nebulised morphine 10 mg or IV morphine 2 mg every 5 min for ED trauma pain provided superior analgesia while being associated with a lower rate of adverse events than the IV group (Grissa 2015 **Level II**, n=300, JS 5). C_{max} following administration of morphine via a standard

nebuliser occurred within 10 min but bioavailability was low with a mean of only 5% (Masood 1996 **PK**). Bioavailability may be improved (up to 59–100%) with C_{max} occurring at 2 min using specific pulmonary-medication delivery systems (Dershwitz 2000 **PK**; Ward 1997 **PK**).

Bioavailability of inhaled fentanyl is significantly higher and may approach 100% (Mather 1998 **PK**). The pharmacokinetic profiles of inhaled and IV fentanyl showed similar peak arterial concentrations and areas under the curve (Macleod 2012 **Level II**, n=10, JS 5). The time to C_{max} was slightly shorter for inhaled vs IV fentanyl (20.5 vs 31.5 s). As is with other nebulised medications, mode of delivery and specifically achieving a particle size small enough to reach the pulmonary alveoli, but large enough to not be expired, is important for absorption (Thompson 2016 **Level I** [PRISMA], 7 RCTs, n=583). Use of breath actuated atomisers may reduce the leak of drug to the general environment while allowing the clinician to establish total dose delivered.

Nebulised fentanyl provides analgesia comparable to IV morphine for acute pain management in a variety of settings with the advantages of lower adverse effect profile, noninvasive delivery and rapid onset (Thompson 2016 **Level I** [PRISMA], 7 RCTs, n=583). Nebulised fentanyl in the ED setting for adults provided analgesia for acute limb trauma that was noninferior to IV morphine (Farahmand 2014 **Level II**, n=90, JS 5). Using a breath actuated inhaler delivering atomised fentanyl provided faster onset of and superior analgesia to IV morphine for acute abdominal pain (Deaton 2015 **Level II**, n=40, JS 5). For renal colic, IV fentanyl provided better analgesia than nebulised fentanyl (Imamoglu 2017 **Level II**, n=117, JS 5).

In children requiring pain relief in an ED, nebulised fentanyl was as effective as IV fentanyl (Miner 2007 **Level II**, n=41, JS 3). See also Section 10.4.4.4.

5.5.4.2 | Other analgesic medications

Nebulised ketamine and dexmedetomidine have been trialled for paediatric pre-medication and may contribute to improved postoperative analgesia (Zanaty 2015 **Level II**, n=60, JS 5).

See Section 4.5 for inhaled N_2O and methoxyflurane.

KEY MESSAGES

1. Intranasal, sublingual and buccal fentanyl preparations are effective treatments for breakthrough pain in cancer patients (**U**) (**Level I** [Cochrane Review]) with similar efficacy to IV administration (**U**) (**Level I** [PRISMA]) and superiority to oral morphine (**U**) (**Level I**).
2. Intranasal fentanyl is an effective treatment for paediatric acute pain management, with an acceptable adverse effect profile and ease of delivery (**N**) (**Level I**).
3. Intranasal fentanyl provides faster and better analgesia for breakthrough pain in cancer patients than oral transmucosal fentanyl and fentanyl buccal tablets (**U**) (**Level I**).
4. Sublingual sufentanil delivered by a PCA device provided analgesia comparable to IV PCA opioids in a number of acute pain settings (**N**) (**Level II**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Neither transmucosal immediate-release nor transdermal fentanyl preparations should be used in the management of acute pain in opioid-naïve patients because of safety concerns and, in most countries, the lack of regulatory approval for use in other than opioid-tolerant patients (**U**).

5.6 | Epidural analgesia

Epidural analgesia (ie the provision of pain relief by continuous administration of pharmacological agents into the epidural space via an indwelling catheter) is an important technique for the management of acute pain in adults and children, particularly after surgery (Weiss 2018 **NR**) and in women in labour (see Section 9.1.3.3). For epidural and caudal analgesia in children see Sections 10.6.3.1 and 10.6.3.2.

5.6.1 | Efficacy

The difficulty with interpretation of available data is that epidural analgesia is not a single entity but can be provided by a number of pharmacological agents administered into different levels of the epidural space for a wide variety of operations.

5.6.1.1 | Efficacy and outcomes in general

The universal efficacy of epidural analgesia has been well demonstrated. Regardless of analgesic agent used, location of catheter, type of surgery and type or time of pain assessment, epidural analgesia provides better pain relief than parenteral opioid administration (Guay 2019 **Level I** [Cochrane], 69 RCTs, n=4,680; Salicath 2018 **Level I** [Cochrane], 32 RCTs, n=1,716; Guay 2016a **Level I** [Cochrane], 15 RCTs [8 TEA, 2 LEA, 4 mixed, 1 unspecified], n=1,498; Popping 2014 **Level I** [PRISMA], 125 RCTs, n=9,044) (significant overlap of multiple RCTs).

One meta-analysis of epidural analgesia vs systemic opioids via PCA concludes that epidural analgesia provides better pain relief at rest and with movement after all types of surgery; with the exception of epidural analgesia using hydrophilic opioids only (Wu 2005 **Level I**, 50 RCTs, n=3,208). The epidural group has a lower incidence of nausea/vomiting and sedation but a higher incidence of pruritus, urinary retention and motor block than IV PCA. A meta-analysis of epidural analgesia provided with local anaesthetics for at least 24 h vs systemic analgesia after surgery (performed under general anaesthesia) shows reduced mortality with epidural analgesia (3.1 vs 4.9%) (OR 0.60; 95%CI 0.39 to 0.93) (Popping 2014 **Level I** [PRISMA], 125 RCTs, n=9,044), as did a large matched-cohort retrospective audit of administrative data (30-d mortality: 1.7 vs 2.0%) (RR 0.89; 95%CI 0.81 to 0.98) (Wijeysundera 2008 **Level III-2**, n=144,744). The meta-analysis also reports benefits of epidural analgesia on perioperative morbidity with decreased risk of atrial fibrillation, supraventricular tachycardia, deep vein thrombosis, respiratory depression, atelectasis, pneumonia, ileus, PONV, and time to return to normal bowel function. A preceding meta-analysis reported similar results (Guay 2006 **Level I**, 70 RCTs, n unspecified). However, adverse effects of epidural analgesia include hypotension, pruritus, urinary retention and motor block (Popping 2014 **Level I** [PRISMA], 125 RCTs, n=9,044).

With regard to pulmonary outcomes specifically, epidural analgesia vs systemic analgesia reduced rate of pneumonia (OR 0.54; 95%CI 0.43 to 0.68), but also the need for prolonged ventilation or reintubation, improved lung function and blood oxygenation (Popping 2008 **Level I**, 58 RCTs, n=5,904); however, notably a decrease of relative benefit has occurred over time where from 1971 to 2006 the baseline risk of pneumonia in the opioid group has decreased from 34 to 12%, but remained 8% in the epidural group.

5.6.1.2 | Cancer surgery outcomes

Current data do not support a benefit for cancer recurrence or survival through addition of epidural anaesthesia/analgesia to general anaesthesia/systemic analgesia following cancer

surgery; neither overall survival (HR 1.03; 95%CI 0.86 to 1.24) nor progression-free survival (HR 0.88; 95%CI 0.56 to 1.38) are improved (Cakmakkaya 2014 **Level I** [Cochrane], 4 RCTs, n=746). Evidence was graded low to very low and all four studies are secondary data analyses of previously conducted RCTs. In a much larger systematic review including not only RCTs, overall survival was improved by epidural anaesthesia (HR 0.84; 95%CI 0.74 to 0.96), in particular after surgery for colorectal cancer (HR 0.65; 95%CI 0.43 to 0.99) (Chen 2013 **Level III-3 SR**, 14 studies, n≈47,000). However, epidural anaesthesia did not improve recurrence-free survival (HR 0.88; 95%CI 0.64 to 1.22). For gastroesophageal cancer surgery, there is no evidence in favour or against an effect of epidural anaesthesia or analgesia on cancer outcomes (Perez-Gonzalez 2018 **Level I**, 6 RCTs, n=263).

5.6.1.3 | Procedure-specific efficacy

Open abdominal surgery

For intra-abdominal surgery of any kind (including hysterectomies, radical prostatectomies, Caesarean section, colorectal and upper gastrointestinal procedures), epidural analgesia (by continuous infusion [16 RCTs, n=418] or PCEA [16 RCTs, n=451]) vs IV PCA opioids improves pain relief at rest to 6 h by 5.7/100 (95%CI 1.9 to 9.5) (7 RCTs, n=384), 7 to 24 h by 9.0/100 (95%CI 4.6 to 13.4) (11 RCTs, n=558) and beyond 24 h by 5.1/100 (95%CI 0.9 to 9.4) (7 RCTs, n=393) (Salicath 2018 **Level I** [Cochrane], 32 RCTs, n=1,716). There is limited evidence for improvement of pain on movement and coughing based on few RCTs, but no evidence for differences in other outcomes such as mortality, venous thromboembolism, sedation, nausea and vomiting, and respiratory parameters. However, in the epidural group, risk of failure of the analgesic technique is increased (RR 2.48; 95%CI 1.13 to 5.45) (10 RCTs, n=678) as is hypotension requiring intervention (RR 7.13; 95%CI 2.87 to 17.75) (6 RCTs, n=479) and pruritus (RR 2.36; 95%CI 1.67 to 3.35) (8 RCTs, n=492).

Epidural local anaesthetics vs systemic or epidural opioids after abdominal surgery reduce pain on movement (SMD -0.89; 95%CI -1.08 to -0.70; equivalent to 2.5/10) (35 RCTs, n=2,731) (Guay 2016b **Level I** [Cochrane], 128 RCTs, n=8,754). Outcomes with regard to gastrointestinal transit time are improved: time to first flatus (SMD -1.28; 95%CI -1.71 to -0.86; equivalent to 17.5 h) (22 RCTs, n=1,138) and to first stool (SMD -0.67; 95%CI -0.86 to -0.47; equivalent to 22 h) (28 RCTs, n=1,559). There is no effect on vomiting within 24 h (22 RCTs, n=1,154) and gastrointestinal anastomotic leakage (17 RCTs, n=848), but very low-quality evidence on reduced LOS for open (not laparoscopic) surgery (SMD -0.20; 95%CI -0.35 to -0.04; equivalent to 1 d) (30 RCTs, n=2,598).

For a wide range of open and laparoscopic abdominal surgery in adults (6 RCTs, n=310) and children (4 RCTs, n=195), epidural analgesia vs TAPB provides similar analgesia (MD 0.3/10; 95%CI -0.1 to 0.6), but TAPB reduces the risk of hypotension (RR 0.13; 95%CI 0.04 to 0.38) (4 RCTs) and LOS (MD -0.6 d; 95%CI -0.9 to -0.3) (3 RCTs) (Baeriswyl 2018 **Level I** [PRISMA], 10 RCTs, n=505).

After open abdominal surgery in the setting of enhanced-recovery programs (ERAS), TEA vs other analgesic approaches results in no more complications (OR 1.14; 95%CI 0.49 to 2.64) but better analgesia (7 RCTs) and earlier recovery of bowel function (4 RCTs[flatus]; 6 RCTs [stool]) without reducing LOS (7 RCTs) (Hughes 2014 **Level I** [PRISMA], 7 RCTs, n=378).

A large retrospective cohort study after elective colectomy reported that postoperative epidural analgesia significantly reduced mortality at 7 d (OR 0.35; 95%CI 0.21 to 0.59) and 30 d (OR 0.54; 95%CI 0.42 to 0.70) (Wu 2006a **Level III-2**, n=12,817). In patients with COPD undergoing major abdominal surgery, TEA added to general anaesthesia vs general anaesthesia alone did not reduce the incidence of postoperative pneumonia (11 vs 16%), but was associated with decreased 30 d mortality (5 vs 9%) and with improved outcome for postoperative pneumonia (OR 0.5; 95%CI 0.3 to 0.9) (van Lier 2011 **Level III-2**, n=541 [324 epidural]). The beneficial effect of TEA increased with increasing COPD severity.

After major upper abdominal surgery, TEA in combination with NSAIDs and IV nutritional support prevented protein loss vs epidural analgesia alone or PCA with and without nutritional support (Barratt 2002 **Level II**, n=57, JS 3). Similarly, after colonic surgery, epidural analgesia increased the anabolic effect of amino acid infusions in diabetic patients (Lugli 2008 **Level II**, n=12, JS 3) and reduced whole body protein breakdown (Lattermann 2007 **Level II**, n=20, JS 2). Epidural anaesthesia/analgesia vs general anaesthesia/systemic analgesia reduced insulin-resistance only in patients who were insulin-resistant preoperatively (Donatelli 2007 **Level II**, n=60, JS 2).

After abdominal cancer surgery, continuous TEA vs continuous IT thoracic analgesia resulted in similar efficacy and adverse effects (Mercadante 2008 **Level II**, n=60, JS 3). After open gastrectomy, TEA (PCEA) was superior to IT morphine combined with IV PCA opioids for all relevant outcomes including analgesia, mobilisation, bowel recovery and pulmonary complications (Lee 2014b **Level II**, n=64, JS 3) and was superior to IV PCA morphine with regard to pain control, gastrointestinal recovery and hospital LOS (Zhu 2013 **Level II**, n=67, JS 2). Compared to continuous wound infiltration with local anaesthetics in fast-track open colectomy, epidural analgesia reduced pain scores on mobilisation until hospital discharge, reduced time to return of bowel function and tolerance of a complete diet, improved sleep quality and reduced hospital LOS (4 vs 5.5 d) (Jouve 2013 **Level II**, n=50, JS 5). These benefits were not demonstrated in another, similar RCT (Bertoglio 2012 **Level II**, n=106, JS 3).

Laparoscopic colectomy

After laparoscopic colectomy, TEA is rarely used in the USA (2.14%) (Halabi 2014 **Level III-2**, n=191,576). After laparoscopic colectomy, TEA vs IV PCA opioids improves pain at rest (2 RCTs, n=110) and on walking at POD 1 and 2 (2 RCTs, n=110) and time to first bowel opening (4 RCTs, n=190), but increases LOS (WMD 0.73 d; 95%CI 0.24 to 1.23) (8 RCTs) and total complication rate (OR 1.57; 95%CI 1.07 to 2.29) (8 RCTs) (Perivoliotis 2019 **Level I** [PRISMA], 8 RCTs, n=492).

Similarly, in a large case-matched analysis, TEA increased LOS by 0.6 d, hospital charges by USA$ 3,732.71 and higher rates of urinary tract infection without any clinical benefits (Halabi 2014 **Level III-2**, n=191,576). Outcomes were inferior with epidural vs IT analgesia or IV PCA (Levy 2011 **Level II**, n=99, JS 3). TEA also did not improve long-term survival in this setting, but increased LOS (median length 5 d vs 3 d with IV PCA) (Day 2012 **Level III-2**, n=424).

Hepatic surgery

For hepatic surgery, there is ongoing debate on the value of epidural analgesia. A large USA survey showed the technique is infrequently used in 5.9% of cases (Rosero 2014 **Level IV**, n=68,028).

Epidural analgesia vs IV PCA after open hepatectomy improves pain control at rest at 24 h (MD 0.59/10; 95%CI 0.30 to 0.88) (3 RCTs, n= 243) and with movement at 48 h (MD 0.95/10; 95%CI 0.31 to 1.60) (2 RCTs, n=98) with no difference in LOS (2 RCTs), complications (overall and analgesia-related) (2 RCTs) nor effect on transfusion (2 RCTs) (Li 2019 **Level I** [PRISMA], 4 RCTs, n=278).

However, wound catheters vs epidural analgesia for open hepatectomy result in similar pain intensity on POD 1 and only slightly worse on POD 2 (WMD 0.29; 95%CI 0.09 to 0.49) (3 RCTs) with less opioid requirements (WMD -6.29; 95%CI -7.92 to -4.65) (2 RCTs, n=176) and faster functional recovery (WMD −0.73; 95%CI −1.13 to −0.32) (3 RCTs) and no other differences in complications (Gavriilidis 2019 **Level I** [PRISMA], 3 RCTs, n=240).

Applying propensity-score matching techniques to a cohort of patients after hepatectomy, there was an association of epidural anaesthesia/analgesia with higher need for blood transfusion and slightly longer hospital LOS (Rosero 2014 **Level III-2**, n=1,604).

Compared to IT morphine with subsequent IV PCA fentanyl, TEA was not superior with the exception of pain at 12 h postoperatively and reduced blood loss (Kasivisvanathan 2014 **Level III-2**, n=73). However, an RCT found significantly improved analgesia and a 50% opioid-sparing effect

(Mondor 2010 **Level II**, n=44, JS 5). Similarly, after live liver donation, TEA vs IV PCA opioids improved analgesia but no other outcomes (Clarke 2011 **Level III-2**, n=228).

Abdominal aortic surgery

After open abdominal aortic surgery in comparison with systemic opioid administration (Guay 2016a **Level I** [Cochrane], 15 RCTs [8 TEA, 2 LEA, 4 mixed, 1 unspecified], n=1,498), epidural analgesia reduces:

- Pain scores on movement POD 1 (MD -1.78/10; 95%CI -2.32 to -1.25) (3 RCTs, n=162), POD 2 (3 RCTs, n=155) and POD 3 (2 RCTs, n=105);
- Time to tracheal extubation (SMD -0.42; 95%CI -0.70 to -0.15; equivalent to 36 h mean reduction) (8 RCTs, n=975);
- Time spent in the ICU (SMD -0.23 (95% CI -0.41 to -0.06); equivalent to 6 h mean reduction) (3 RCTs, n=523);
- Acute respiratory failure (RR 0.69; 95%CI 0.56 to 0.85); NNT 8 [95%CI 6 to 16]) (6 RCTs, n=861);
- Myocardial infarction (RR 0.54; 95%CI 0.30 to 0.97; NNT 28 [95%CI 19 to 1423]) (3 RCTs, n=503);
- Gastrointestinal bleeding (OR 0.20; 95% CI 0.06 to 0.65); NNT 32 [95%CI 27 to 74]) (4 RCTs, n=487).

However, the reduced morbidity does not translate to a difference in mortality between epidural vs systemic opioids use (RR 1.06; 95%CI 0.60 to 1.86) (14 RCTs, n=1,383).

Studies not included in this meta-analysis support these results: TEA vs systemic opioids improved pain, mobility and time to oral intake (Salman 2013 **Level III-1**, n=80) and pain and postoperative respiratory function in COPD patients (Panaretou 2012 **Level III-2**, n=30). After endoluminal aortic aneurysm repair, TEA provided better analgesia than IV opioids (Sen 2014 **Level III-2**, n=32). However, in a fast-track setting for abdominal aortic aneurysm repair, TEA was similarly effective vs continuous local anaesthetic wound infiltration with no effects on overall outcome (Renghi 2013 **Level II**, n=60, JS 3).

Gynaecological surgery

In gynaecological surgery, epidural ropivacaine infusion provided only slightly better analgesia in the first 8 h postoperatively vs wound infiltration/infusion of ropivacaine with no other clinically relevant improvements (Ammianickal 2018 **Level II**, n=102, JS 3; Fassoulaki 2014 **Level II**, n=80, JS 3). After abdominal hysterectomy (midline incision), epidural analgesia increased duration of postoperative analgesic use, nonserious postoperative complications and LOS vs parenteral opioids (Belavy 2013 **Level III-2**, n=257). Similarly, after uterine artery embolisation for uterine fibroids, epidural analgesia increased complications but reduced pain scores at high costs (179 Euro for 1/10 pain score reduction) (van der Kooij 2013 **NR**). After abdominal hysterectomy, TAPB (bupivacaine 0.25% 15 mL bilaterally)/placebo/placebo provided the best pain relief and the lowest rescue morphine requirements vs placebo/epidural analgesia/placebo (bolus injections of 8 mL bupivacaine 0.125% every 6 h) and vs placebo/placebo/parenteral (alternating diclofenac, tramadol) analgesia (Mathew 2019 **Level II**, n=60, JS 4). In contrast, single bolus TAPB was inferior to single bolus epidural analgesia in the same setting with higher pain intensity 6 to 24 h and higher rescue tramadol requirements (68.8 mg [SD 25.5] vs. 5.3 mg [SD 11.6]) (Raghvendra 2016 **Level II**, n=60, JS 3).

After abdominal hysterectomy, epidural analgesia and IT morphine 200 mcg provided acceptable analgesia over 24 h, but IT morphine resulted initially (0 to 16 h) in better pain relief and lower opioid requirements (Hassan 2017 **Level II**, n=32, JS 3).

Urologic surgery

After radical retropubic prostatectomy, TEA vs patient-controlled local anaesthetic wound infusion reduced pain scores upon coughing and opioid requirements, with better preservation of expiratory muscle strength (Fant 2011 **Level II**, n=50, JS 5). However, a cohort study found an increased median hospital LOS with use of epidural analgesia for this operation (6 vs 7 d), which remained significant after adjusting for complications (Mir 2013 **Level III-2**, n=239). Malignancy recurrence based upon prostate-specific antigen change was more common in the epidural group (14.8 vs 4.8%). TEA had no effect on blood loss or transfusion rates (Baumunk 2014 **Level II**, n=235, JS 2).

Thoracic surgery

Following thoracotomy, there is moderate-quality evidence that shows comparable analgesic efficacy at rest and after coughing over 24 (6 RCTs, n=365) and 48 h (5 RCTs, n=346) with TEA vs PVB (Yeung 2016 **Level I** [Cochrane], 14 RCTs, n=698). There is low to very low-quality evidence that shows no significant difference in mortality and major complications. There is moderate-quality evidence that PVB has a superior minor complication risk vs TEA including hypotension (RR 0.16; 95%CI 0.07 to 0.38) (8 RCTs, n=445), nausea and vomiting (RR 0.48; 95%CI 0.30 to 0.75) (6 RCTs, n=345), pruritus (RR 0.29; 95%CI 0.14 to 0.59) (5 RCTs, n=249) and urinary retention (RR 0.22; 95%CI 0.11 to 0.46) (5 RCTs, n=258). These results are consistent with a parallel meta-analysis showing that continuous PVB reduces the incidence of nausea, vomiting, hypotension and urinary retention vs thoracic epidural analgesia, wound infiltration or IV opioids with comparable post-cardiothoracic surgery analgesia (Scarfe 2016 **Level I** [PRISMA], 23 RCTs, n= 1,120) (10 RCTs overlap with Yeung 2016).

For oesophagectomy, TEA vs systemic analgesia does not improve pain relief at 24 h (MD 0.89; 95%CI −0.47 to 2.24) (2 RCTs & 2 studies) or 48 h (MD 0.15; 95%CI −0.60 to 0.91) (2 RCTs & 2 studies) nor does it reduce the rate of pulmonary complications (RR 1.69; 95%CI 0.86 to 3.29) (2 RCTs & 2 studies) (Visser 2017 **Level III-2 SR**, 5 RCTs & 5 studies, n=891). Technical failure with TEA occurs in 17 to 22%. These findings are supported by a subsequent systematic review (Hughes 2018 **Level I** [PRISMA], 3 RCTs [oesophagectomy], n=93) (2 RCTs overlap).

After lung resection, postoperative TEA reduced mortality at 7 d (OR 0.39; 95%CI 0.19 to 0.80) and 30 d (OR 0.53; 95%CI 0.35 to 0.78) in a retrospective cohort study (Wu 2006b **Level III-2**, n=3,501). TEA in patients after lobectomy resulted in better pain relief and pulmonary function vs IV morphine (Bauer 2007 **Level II**, n=93, JS 5).

After video-assisted thoracic surgery (VATS), PCEA achieved similar pain control as IV fentanyl PCA/low-dose ketamine with no difference in analgesia-related adverse effects (Tseng 2019 **Level II**, n=74, JS 3).

Following open thoracotomy, epidural anaesthesia reduces the incidence of CPSP three to 18 mth following surgery vs systemic analgesia (OR 0.52; 95%CI 0.32 to 0.84; NNT 7) (7 RCTs, n=499) (Weinstein 2018 **Level I** (Cochrane), 63 RCTs, n=3,027).

Cardiac surgery

A meta-analysis of epidural analgesia vs multiple comparators for cardiac surgery with or without cardiopulmonary bypass finds insufficient evidence to show an effect of epidural analgesia vs peripheral nerve blocks (4 RCTs), interpleural analgesia (1 RCT) or wound infiltration (1 RCT) (Guay 2019 **Level I** [Cochrane], 69 RCTs, n=4,680). In comparison to systemic analgesia, there is a reduction of pain at rest and on movement for the first 72 h eg from 6 to 8 h (SMD -1.35/10; 95%CI -1.98 to -0.72) (10 RCTs, n=502) and an increase in hypotension (RD 0.21; 95%CI 0.09 to 0.33) (17 RCTs, n=870) not leading to increased need for inotropes or vasopressors (RD 0.00; 95%CI -0.06 to 0.07) (23 RCTs, n=1,821). With regard to other outcomes, there is no difference in mortality, cerebrovascular accidents or pneumonia, there may be a reduction in myocardial infarction at

0 to 30 d, respiratory depression (RD -0.03; 95%CI -0.05 to -0.01) (21 RCTs, n=1,736) and risk of atrial fibrillation or atrial flutter at 0 to 2 wk (RD -0.06; 95%CI -0.10 to -0.01) (18 RCTs, n=2,431). A difference in mortality is reported in a meta-analysis including RCTs and case-matched studies; here epidural anaesthesia/analgesia reduces mortality (59/3123 [1.9%] vs 108/3260 [3.3%]) (RR 0.65; 95%CI 0.48 to 0.86; NNT 70) and rate of myocardial infarction (67/2785 [2.4%] vs 108/2933 [3.7%]) (RR 0.68; 95% CI 0.51 to 0.90]; NNT 78) (Landoni 2015 **Level III-2 SR**, 57 studies, n=6,383) (40 RCTs overlap).

In smaller studies, high TEA improved left ventricular function (Schmidt 2005 **Level III-3**, n=37) and increased stroke volume index and central venous oxygenation in elderly cardiac surgery patients, without an increase in heart rate or mean arterial pressure (Jakobsen 2012 **Level II**, n=60, JS 3). Prior to CABG surgery, high TEA improved myocardial oxygen availability in patients with ischaemic heart disease (Lagunilla 2006 **Level II**, n=52, JS 4) and partly normalised myocardial blood flow in response to sympathetic stimulation (Nygard 2005 **Level III-3**, n=20). After CABG surgery, high TEA postoperatively reduced insulin requirements and hyperglycaemia (Greisen 2013 **Level II**, n=42, JS 3) (included in Guay 2019). However, TEA did not reduce the ICU LOS or improve the quality of recovery in the ICU (Nielsen 2012 **Level II**, n=60, JS 3). The discussion on the overall value of epidural analgesia after cardiac surgery continues, with concerns regarding anticoagulation risk being a key factor (Ziyaeifard 2014 **NR**).

Rib fractures

Compared to thoracic epidural analgesia, systemic IV analgesia provides inferior analgesia for rib fractures (2 RCTs & 2 studies, n=205) (Peek 2019 **Level III-2 SR** [PRISMA], 8 RCTs & 11 studies, n=2,081). There was no significant difference in secondary outcomes such as duration of mechanical ventilation (3 RCTs & 1 study), ICU LOS (4 RCTs & 4 studies), hospital LOS (4 RCTs & 4 studies) and pulmonary complications (4 RCTs & 6 studies). Thoracic epidural analgesia provides similar analgesia to continuous intercostal (1 RCT & 1 study) and paravertebral blocks (1 RCT & 1 study) with no significant difference in duration of mechanical ventilation, ICU LOS, hospital LOS and pulmonary complications (2 to 3 studies per outcome).

In patients with multiple traumatic rib fractures, provision of TEA with local anaesthetic reduces the duration of ventilation vs other forms of analgesia (including LEA) (Carrier 2009 **Level I**, 8 RCTs, n=232) (2 RCTs overlap with Peek 2019); however, mortality and ICU LOS is not different in pooled analysis of all routes of epidural administration vs parenteral opioids and hypotension was more frequent in the epidural groups when TEA with local anaesthetic was used.

After blunt chest trauma with three or more rib fractures, the use of TEA was more common in USA trauma centres than in nontrauma centres; the use of TEA vs other methods of analgesia reduced adjusted mortality at 30 d (OR 0.08; 95%CI 0.01 to 0.43), 90 d (OR 0.09; 95%CI 0.02 to 0.42) and 365 d (OR 0.12; 95%CI 0.04 to 0.42) (n=100 [TEA]) (Gage 2014 **Level III-2**, n=836). See also Section 8.3.

Orthopaedic surgery

Spinal fusion

After spinal fusion, patient controlled epidural analgesia (PCEA) vs IV PCA opioids provides better analgesia on POD 1 (MD −0.47/10; 95%CI −0.74 to −0.20) and POD 2 (MD −0.66; 95%CI −1.14 to −0.19), but not on POD 3 (Tian 2015 **Level I**, 8 RCTs, n=482). There are no differences in PONV rates, but PCEA increases rates of pruritus (RR 1.53; 95%CI 1.08 to 2.6) and paraesthesia (RR 3.34; 95%CI 1.12 to 9.98). A parallel meta-analysis not differentiating results as detailed as the previous one finds similar results for analgesia overall, and no differences in all pooled adverse effects (Lu 2015 **Level I**, 9 RCTs, n=436) (7 RCTs overlap).

In RCTs not included in these meta-analyses, epidural analgesia with levobupivacaine reduced pain scores, opioid consumption, nausea, blood loss and time to first stool vs IV opioid

analgesia (Servicl-Kuchler 2014 **Level II**, n=81, JS 5). Similarly, after major spinal surgery, epidural analgesia (levobupivacaine/fentanyl/ adrenaline) vs systemic opioids reduced pain and nausea, permitted earlier mobilisation and increased satisfaction with less intraoperative and postoperative blood loss and reduced stress response markers (glucose, cortisol, IL-1beta, IL-6, and IL-10) (Ezhevskaya 2013 **Level II**, n=85, JS 2). However, when added to systemic multimodal analgesia, TEA did not provide a significant opioid-sparing effect (Choi 2014 **Level II**, n=39, JS 5).

Lower limb arthroplasty (TKA and THA)

After THA and TKA, lumbar epidural analgesia (LEA) provides better pain relief than parenteral opioids, in particular with movement (Choi 2003 **Level I** [Cochrane], 13 RCTs, n unspecified). A subsequent study showed that epidural analgesia vs systemic opioids reduced inflammatory response measured by a number of parameters after TKA (Chloropoulou 2013 **Level II**, n=56, JS 3).

However, in comparison to peripheral nerve blocks (FNB and ACB by single-injection or catheter), LEA does not improve pain following TKA for 0 to 48 h (7 & 8 RCTs), but is associated with increased PONV (RR 1.65; 95 %CI 1.20 to 2.28) (9 RCTs, n=433), hypotension (RR 1.76; 95 %CI 1.26 to 2.45) (9 RCTs, n=551) and urinary retention (RR 4.51; 95%CI 2.27 to 8.96) (7 RCTs, n=331) (Gerrard 2017 **Level I** [PRISMA], 12 RCTs, n=670). In comparison to local infiltration analgesia (LIA) by single-injection or via catheter for TKA and THA, LEA has similar analgesic effects at rest for <24 h (9 RCTs), but LIA achieves better analgesia at 48 h (MD −1.08/10; 95%CI −1.86 to −0.29)) and 72 h (MD −0.82/10; 95%CI −1.24 to −0.4) more so in TKA (6 RCTs, n=446) (Yan 2016 **Level I**, 9 RCTs [6 TKA & 3 THA], n=537) (0 RCT overlap). Pain on movement was similar overall at <24 h (4 RCTs), but better controlled by LIA at 48 h for TKA with better range of knee movement at all time points (3 RCTs).

For comparisons with other regional analgesic techniques, see also Section 5.8.

Vascular surgery of the lower limbs

Used in vascular surgery of the lower limbs, LEA improved outcome by reducing incidence of graft occlusion (Christopherson 1993 **Level II**, n=100, JS 3; Tuman 1991 **Level II**, n=80, JS 1). However, these findings have not been confirmed by other investigators in retrospective reviews (Schunn 1998 **Level III-2**, n=294; Pierce 1997 **Level III-1**, n=423), although a subsequent data base analysis of the USA National Surgical Quality Improvement Program (NSQIP) showed a number of outcome advantages (re graft failure, cardiac events, postoperative pneumonia) with epidural (and spinal) over general anaesthesia (Singh 2006 **Level III-2**, n=14,788).

For effects of epidural analgesia on pain after amputation, see Section 8.1.5.1.

5.6.1.4 | Level of administration

TEA is widely used for the treatment of pain after major abdominal and thoracic surgery. Administration of local anaesthetics into the thoracic epidural space resulted in improved bowel recovery after abdominal surgery, while these benefits are not consistent with lumbar administration (Jorgensen 2000 **Level I** [Cochrane], 22 RCTs, n=1,023). In a direct comparison between TEA and LEA for thoracotomy, TEA vs LEA reduced pain scores and opioid requirements as well as hypotension, bradycardia, atelectasis and need for ICU treatment (Sagiroglu 2014 **Level II**, n=134, JS 4). Benefits of epidural analgesia after abdominal aortic surgery were found with impact on nonanalgesic outcomes significant for TEA, but not LEA (see above) (Nishimori 2012 **Level I** [Cochrane], 15 RCTs, n=1,297). In patients with multiple traumatic rib fractures, provision of TEA with local anaesthetic reduced the duration of ventilation vs other forms of analgesia including LEA (Carrier 2009 **Level I**, 8 RCTs, n=232). In gynaecological surgery, TEA provided better pain relief vs LEA only when the incision extended above the umbilicus; TEA led to less motor block but more pruritus (Richman 2007 **Level II**, n=103, JS 5). Motor block with epidural analgesia (mainly by

infusion of bupivacaine 0.1%/fentanyl 2 mcg/mL) occurred in 36.5% of patients with the highest incidence when the catheter was placed at levels L2/3 and L 3/L4 (Ahmed 2016 **Level IV**, n=123).

TEA permits early removal of urinary catheters in many patients vs LEA; rates of urinary retention are variably reported as 6.6% (Tripepi-Bova 2013 **Level IV**, n=61), 11.9% (vs 2.2% after TEA was discontinued) (Stubbs 2013 **Level III-2**, n=118) and 26.7% (vs 12.4% in historic controls) (Hu 2014 **Level III-3**, n=101). Post removal of the urinary catheter, effective bladder emptying took hours to normalise (defined as post-void volumes <200 mL) in patients who received TEA, however without need for recatheterisation; this effect was prolonged when the urinary catheter was removed early on the morning after surgery rather than remaining *in situ* for the duration of TEA therapy (345 min ± 169 vs 207 min ± 122) (Zaouter 2012 **Level II**, n=205, JS 2). TEA for thoracotomy did not change the post-void volume from the preoperative findings in men and women (Wuethrich 2011b **Level III-3**, n=26); only three men >50 y with prostrate hypertrophy had post-void volumes >100 mL. However, in women undergoing nephrectomy, early removal of the urinary catheter under TEA led to an increase in post-void residual volume (median 5 vs 220 mL) and negatively affected other parameters of bladder emptying (detrusor pressure, maximum flow rate, voided volume) (Wuethrich 2011a **Level III-3**, n=13); the authors suggest that this necessitates indwelling or intermittent catheterisation or monitoring.

5.6.1.5 | Patterns of administration

Routinely, epidural analgesia is maintained by continuous infusion. More recently, programmed intermittent epidural bolus (PIEB) has been suggested as a superior technique, based on data in labour analgesia (see Section 9.1.3.3). After TKA, PIEB vs continuous infusion (both delivering 3 mL/h of 0.125% bupivacaine/0.005% morphine) reduced pain scores and rescue analgesia requirements (Kang 2013 **Level II**, n=53, JS 2). After major abdominal or gynaecological surgery, PIEB TEA vs continuous TEA infusion (both techniques delivering 6 mL/h ropivacaine 0.2%) resulted in reduced PCEA requirements in the first 48 h postoperatively (median 10 mL [IQR 2 to 28] vs 28 mL [12 to 64]) without any other clinically relevant benefits (Wiesmann 2018 **Level II**, n=110, JS 5). In a similar RCT following open gynaecological surgery, PIEB TEA vs continuous TEA infusion (both delivering 4 mL/h ropivacaine 0.2%/fentanyl 2 mcg/mL) resulted in slightly reduced PCEA requirements, but also improved pain control from 3 to 48 h (Satomi 2018 **Level II**, n=57, JS 5).

5.6.2 | Medicines used for epidural analgesia

Differences in analgesic effect, duration and adverse effects depend upon the various local anaesthetic, opioid and adjuvant medicines used in epidural analgesia.

5.6.2.1 | Local anaesthetics

For epidural infusions, dose-ranging studies established that 0.2% ropivacaine was a suitable concentration (Scott 1995 **Level II**, n=40, JS 3; Schug 1996 **Level II**, n=50, JS 4). Therefore, most investigators compare infusions of bupivacaine or levobupivacaine at 0.1 or 0.125% with ropivacaine 0.2%, which removes any imbalance in comparative potency. For more information on differences in efficacy and adverse effects between the local anaesthetics used for epidural analgesia see Section 4.4.

5.6.2.2 | Opioids

Opioids alone via the epidural route appear to be of limited benefit. In particular, when administered via TEA, opioids fail to demonstrate any advantage over parenteral opioids except for a slight reduction in the rate of atelectasis (Ballantyne 1998 **Level I**, 48 RCTs, n unspecified) with no benefit with regard to bowel recovery (Jorgensen 2000 **Level I** [Cochrane], 22 RCTs, n=1,023). On the basis of the available studies, the benefits of administering lipophilic opioids alone by the epidural route appear to be marginal, or unproven in the case of upper abdominal surgery, and in many situations will not outweigh the risks of the more invasive route of administration. For a detailed discussion see (Wheatley 2001 **NR**) and Section 4.3.2.

For information on the epidural use of morphine, ER morphine, pethidine, fentanyl, alfentanil, sufentanil, diamorphine and hydromorphone see also Section 4.3.2.

5.6.2.3 | Local anaesthetic-opioid combinations

Combinations of low concentrations of local anaesthetic agents and opioids provide consistently superior pain relief vs either of the medications alone (Curatolo 1998 **Level I**, 18 RCTs [fentanyl], n unspecified). Addition of fentanyl to a continuous epidural infusion of ropivacaine reduced the rate of regression of sensory block after orthopaedic (n=80) and abdominal gynaecological surgery (n=39) (Kanai 2007 **Level II**, n=119, JS 3) and decreased the discontinuation of postoperative epidural infusion due to lack of efficacy (Scott 1999 **Level II**, n=244, JS 4).

Addition of 4 mcg/mL of fentanyl to levobupivacaine 0.125% improved quality of analgesia and reduced the stress response (ACTH, cortisol and prolactin levels) after TKA vs plain levobupivacaine (Bayazit 2013 **Level II**, n=40, JS 4). Addition of 0.5 mcg/mL sufentanil to 0.1% ropivacaine vs higher sufentanil concentrations and 4 mcg/mL fentanyl resulted in no difference in quality of analgesia after arthroplasty and had the lowest rate of pruritus (Jeon 2011 **Level II**, n=80, JS 3). The MLAC of epidural lidocaine of 0.785% (95%CI 0.738 to 0.864) was reduced by 2 mcg/mL fentanyl to 0.596% (95%CI 0.537 to 0.660) and by 3 mcg/mL to 0.387% (95%CI 0.329 to 0.446) (up-down sequential titration) (Zhang 2012 **Level III-1**, n=120).

5.6.2.4 | Adjuvant medicines

The efficacy of adding of adjuvant medicines such as adrenaline (epinephrine), clonidine, dexmedetomidine, ketamine, midazolam, neostigmine and magnesium to solutions used for epidural analgesia has also been investigated (see Chapter 4).

5.6.3 | Patient-controlled epidural analgesia

The use of PCEA is based on similar concepts as for other patient-controlled techniques. It has been shown to be safe and effective in standard ward settings (Golster 2014 **Level IV**, n=4,663; Kim 2013 **Level IV**, n=2,276; Tan 2011 **Level IV**, n=928; Liu 2010 **Level IV**, n=3,736).

5.6.3.1 | Comparison with continuous epidural infusions

A systematic review comparing PCEA, continuous epidural infusions and IV PCA opioids after surgery showed that both forms of epidural analgesia (with the exception of hydrophilic opioid-only epidural regimens) provide better pain relief with rest and with activity than PCA opioids (Wu 2005 **Level I**, 50 RCTs, n=3,208). However, analgesia with a continuous epidural infusion is superior to PCEA, countered by higher incidence of nausea, vomiting and motor block.

For specific procedures, results of PCEA vs continuous infusion are conflicting. After colonic resection, PCEA was superior to continuous epidural infusion with regard to pain control, requirements for top-ups and systemic analgesia as well as patient satisfaction (Nightingale 2007 **Level II**, n=205, JS 5). In contrast, comparisons of PCEA and continuous epidural infusions for pain relief after thoracotomy using both high (0.5%) and low (0.15%) concentrations of levobupivacaine showed no differences in quality of analgesia, morphine consumption or satisfaction; more patients in the high concentration continuous epidural infusion group had significant motor block (Dernedde 2008 **Level II**, n=82, JS 3).

5.6.3.2 | Concurrent background (continuous) infusions

The addition of a continuous background infusion to PCEA using bupivacaine and fentanyl following gastrectomy resulted in better dynamic pain scores, with higher total doses and a greater incidence of pruritus than PCEA-bolus dose only (Komatsu 1998 **Level II**, n=40, JS 2). The use of a night-time-only background infusion with PCEA bupivacaine-fentanyl, also post gastrectomy, resulted in better sleep, but total cumulative doses were similar and pain scores were only better in the morning of postoperative d 2 (Komatsu 2001 **Level II**, n=40, JS 2). A Swedish case series over 7 y (Golster 2014 **Level IV**, n=4,663) and a USA case series (Liu 2010 **Level IV**, n=3,736) describe successful and safe use of PCEA with a background infusion.

Other studies have found no improvement in pain relief with background infusions. After lower abdominal surgery there was no difference in pain scores but higher total cumulative doses and incidence of adverse effects when a background infusion was added to PCEA with ropivacaine and fentanyl (Wong 2000 **Level II**, n=42, JS 2). The addition of a background infusion to bupivacaine-fentanyl PCEA did not improve pain relief after pelvic reconstruction (Nolan 1992 **Level II**, n=23, JS 5).

5.6.3.3 | Medications used in postoperative patient-controlled epidural analgesia

The medications used for PCEA are typically the same as those used for continuous epidural infusions. Conclusions about the efficacy of different medications and medication combinations administered via PCEA are difficult to make because of the wide variety of analgesic agents and concentrations used in the various studies.

5.6.4 | Adverse effects

5.6.4.1 | Neurological injury

Permanent neurological damage is the most feared complication of epidural analgesia.

A systematic review identified 647 cases of epidural haematoma (n=387) and abscess (n=260) after neuraxial anaesthesia (Bos 2018 **Level IV SR**, n=409 [reports]). Epidural anaesthesia was related to 58% of haematomas and 83% of abscesses. After epidural haematoma, 28% had partial and 25% no recovery. After epidural abscess, 21% had partial and 11% no recovery. Persistent neurological deficits were correlated with the severity of the initially presenting neurology.

A retrospective survey from Sweden put the risk of a severe neurological complication after obstetric epidural analgesia at 1 per 25,000 and for all other patients at 1 per 3,600; 67% of events resulted in permanent neurological deficit (Moen 2004 **Level IV**, n=450,000). It also identified osteoporosis as a previously neglected risk factor. A review of data from publications reporting adverse effects after obstetric epidural analgesia reported a risk estimate of 1 per 240,000 for persistent neurological injury and 1 per 6,700 for transient (resolution within 12 mth) neurological symptoms (Ruppen 2006a **Level IV SR**, 27 studies, n≈1.37 million).

A review of data from published studies of the risk of neurological injury associated with epidural and other regional anaesthesia and analgesia techniques differentiated between the risk of permanent neurological injury (deficit lasting >12 mth) and transient neuropathy (Brull 2007 **Level IV SR**, 32 studies, n unspecified). This review focussed on adverse neurological sequelae associated with the various regional techniques and did not address the overall risk of epidural haematoma or abscess. The incidence of transient neuropathy (radiculopathy) after epidural anaesthesia was estimated to be 2.19 per 10,000 (95%CI 0.88 to 5.44) (Brull 2007 **Level IV SR**, 4 studies [epidural], n unspecified). The risk of permanent neurological injury was lower and the incidences reported in the studies included in this review ranged from 0 to 7.6 per 10,000. The rates of paraplegia and cauda equina syndrome associated with epidural anaesthesia were estimated to be 0.09 per 10,000 (95%CI 0.04 to 0.22) and 0.23 per 10,000 (95%CI 0.14 to 0.39) respectively.

A project in the UK (NAP3) assessed the incidence of neurological complications in an estimated 97,925 adult patients with perioperative epidural catheters (Cook 2009 **Level IV**). Depending on the inclusion or exclusion of cases with unlikely causation, pessimistic and optimistic assessments were published. The incidence of permanent injury was pessimistically assessed as 17.4 per 100,000 (95%CI 7.2 to 27.8; 1 in 5,800) and optimistically as 8.2 per 100,000 (95%CI 3.5 to 16.1; 1 in 12,200). Laminectomy was performed with an incidence of 12.3 per 100,000 cases (95%CI 6.3 to 21.4; 1 in 8,100). Paraplegia was caused in 6.1 per 100,000 (95%CI 2.2 to 13.3; 1 in 16,400) in the pessimistic vs 1.0 per 100,000 (95%CI 1.0 to 5.7) in the optimistic model.

Audit data from a single (nonobstetric) tertiary institution of epidural catheters inserted over a 16 y period for postoperative pain relief found two spinal haematomas and six epidural abscesses; only one patient (with an epidural abscess) required surgical decompression and no patient suffered any long-term neurological deficit (Cameron 2007 **Level IV**, n=8,210 [epidural catheters]). The largest published audit of patients undergoing arthroplasty with epidural analgesia at one institution described no persistent neurologic deficit despite four patients developing epidural haematoma and two requiring surgical compression (Pumberger 2013 **Level IV**, n=62,856). Another audit at a single institution reported 1 epidural haematoma, but 57 postoperative neurologic deficits, which resolved within 3 mth except for one being permanent (unilateral lower limb paraesthesia) (Kang 2014 **Level IV**, n=5,083).

The incidence of transient neuropathy after epidural analgesia in large case series was in the range of 0.013 to 0.023% (Auroy 1997 **Level IV**, n=30,413; Tanaka 1993 **Level IV**, n=40,010; Xie 1991 **Level IV**, n=1,304,214).

5.6.4.2 | Epidural haematoma

A major concern is the development of an epidural haematoma with subsequent, potentially permanent, SCI. A review including case series involving over 1,335,000 patients with epidural analgesia reported seven cases of haematoma (1 per 191,000) (Wulf 1996 **Level IV**). On the basis of this case series, the possible incidence is in the order of 1 per 100,000 at the upper limit of the 95%CI. The Swedish case series quoted above puts the overall risk of epidural haematoma after epidural blockade at 1 per 10,300 (Moen 2004 **Level IV,** n=450,000). A Finnish closed-claims study calculated a risk of 1 per 26,400 (Pitkanen 2013) **Level IV**, n=216 [claims]). An even higher incidence of epidural haematoma (1 per 3,100) has been estimated for epidural analgesia in association with inappropriate low molecular weight heparin (LMWH) dose regimens (Horlocker 2003 **GL**) (see Section 5.9).

A systematic review of the risks of epidural haematoma and neurological injury associated with epidural anaesthesia/analgesia in cardiac, vascular and thoracic surgery patients concluded

that the maximum risks of epidural haematoma were 1 per 1,700, 1 per 1,700 and 1 per 1,400 respectively (Ruppen 2006b **Level IV SR**, 12 studies, n=14,105). However, this was a calculated risk only; there were actually no cases of epidural haematoma reported in the studies used in this analysis and the maximal calculated expected rate of permanent neurological injury associated with epidural haematoma was 1 per 4,600.

In a large USA case series of patients having epidural analgesia perioperatively, seven patients developed haematoma requiring surgical evacuation (1 per 8,921; 95%CI 1/4,330 to 1/22,189) (Bateman 2013 **Level IV**, n=62,450)). In four of the seven patients, management of anticoagulation was not in line with the guidelines of American Society of Regional Anesthesia and Pain Medicine (ASRA) discussed later (see Section 5.9). In a similarly large case series of patients having arthroplasty with an indwelling epidural catheter at one institution, four epidural haematomas occurred (1 per 15,714), of which two required emergency decompression and none resulted in persisting neurological deficits (complete recovery at 6 wk) (Pumberger 2013 **Level IV**, n=62,856). It is of note that all four patients had combined spinal and epidural anaesthesia, took at least one medication affecting coagulation (aspirin, TCA, NSAIDs, clopidogrel) and had preoperative hypertension. Additional risk factors were clopidogrel only discontinued for 4 d in one, thrombocytopenia (70,000/microL) at day of insertion and removal in one and excessive alcohol consumption in two.

In a case series after cardiac surgery, the risk of epidural haematoma was calculated at 1 per 12,000 (95%CI 1 per 2,100 to 1 per 68,000); comparable to an obstetric population (Bracco 2007 **Level IV**, n=1,293). It was described as being in the same risk range as receiving a wrong blood product (or the yearly risk of having a fatal traffic accident in a Western country). A subsequent study including a survey in cardiac surgery identified a risk of epidural haematoma of 1 per 3,552 (95%CI 1 per 2552 to 1 per 5841) (Landoni 2015 **Level IV**, n=88,820 [estimated epidural catheters]).

A review of data from publications reporting adverse effects after obstetric epidural analgesia reported a risk estimate of 1 per 168,000 for epidural haematoma (Ruppen 2006a **Level IV SR**, 27 studies, n≈1.37 million). In a large USA series of obstetric epidural analgesia, no epidural haematoma was found (Bateman 2013 **Level IV**, n=79,837); the haematoma rate in this setting was significantly lower than in the perioperative data from the same series.

Case reports of epidural haematoma after neuraxial blockade (spinal and epidural) have increased from 1994 to 2015, primarily due to increased rates in elderly women (Lagerkranser 2017a **Level IV SR**, n=166). Anticoagulants, in particular heparins, remain an important risk factor, but epidural haematomas occur also in patients with no risk factors and despite following guidelines. 80% present with paresis or paralysis, early MRI scan is the best diagnostic measure and over the period studied, outcomes have improved (Lagerkranser 2017b **Level IV SR**, n=166).

Early diagnosis and, if indicated, immediate decompression (<8 h after the onset of neurological signs) increases the likelihood of partial or good neurological recovery (Horlocker 2003 **GL**). This is confirmed by a case series of epidural haematomas (n=163), which showed worse outcome with decompression delayed >12 h vs earlier decompression (OR 4.5; 95% CI 2.1 to 9.9) (Bos 2018 **Level IV SR**, n=409 [reports]). This is confirmed by a further case series, although some patients operated >24 h regained full motor function (Lagerkranser 2017b **Level IV SR**, n=166).

5.6.4.3 | Infectious complications (including epidural abscess)

Serious neuraxial infections following epidural anaesthesia have previously been reported as rare. However, prospective studies have found rates in the range of 0.015 to 0.05% (Wang 1999 **Level IV**, n=9,232; Rygnestad 1997 **Level IV**, n=2,000; Kindler 1996 **Level IV**, n>13,000). It is of note that in the studies with these high incidences, patients had long durations of epidural catheterisation; the mean duration in patients with an epidural space infection was 11 d, no infection occurred

in any patient whose catheter was *in situ* for <2 d and the majority of patients were immunocompromised (Wang 1999 **Level IV**, n=9,232).

Only 5.5% of 915 cases of epidural abscess published between 1954 and 1997 developed following epidural anaesthesia and analgesia; 71% of all patients had back pain as the initial presenting symptom and only 66% were febrile (Reihsaus 2000 **Level IV**, n=915). The classic triad of symptoms (back pain, fever and neurological changes) was present in only 13% of patients with an epidural abscess (in a study unrelated to epidural catheterisation); diagnostic delays occurred in 75% of these patients and such delays led to a significantly higher incidence of residual motor weakness (Davis 2004 **Level IV**, n=63 [epidural abscesses]).

Audit data showed that of 8,210 patients with epidural catheters over a period of 16 y, six developed epidural abscesses (Cameron 2007 **Level IV**). Only one of these required surgical decompression and they did not suffer any long-term neurological loss. The authors stress the importance of appropriate patient monitoring and early diagnosis using MRI. In five of the six patients diagnosed with an epidural abscess, both fever and epidural insertion site infection were present. They therefore suggested that MRI investigation may be warranted if this combination is present and that urgent investigation is especially indicated if there is a third sign that could indicate an abscess, such as back pain or neurological change (Cameron 2007 **Level IV**, n=8,210). If the diagnosis of epidural abscess can be made before the onset of any neurological deficit, conservative treatment (antibiotics only) may be effective. The presence of severe or increasing back pain, even in the absence of a fever, may indicate epidural space infection and should be investigated promptly.

Thoracic epidural abscesses have been analysed; most common presentations were neurological deficits (68%) (paraparesis 48% and paraplegia 20%), back pain (64%), fever (24%) and loss of bowel or bladder control (16%) (Howie 2018 **Level IV SR** [PRISMA], 25 studies, n=25 [thoracic epidural abscesses]). Recommended diagnostic measures are early MRI scans, laboratory tests (ESR, CRP, blood count and sedimentation rate/C-reactive protein, complete blood count), empiric antibiotics (until abscess culture) and immediate surgical decompression in neurological deficits as immediate surgical compression achieves better recovery than a failed antibiotic course before surgical decompression.

A review of data from publications reporting adverse effects after obstetric epidural analgesia reported a risk estimate of 1 per 145,000 for epidural space infection (Ruppen 2006a **Level IV SR**, 27 studies, n≈1.37 million).

Septic meningitis has also been associated with neuraxial anaesthesia and analgesia, although most cases were associated with spinal or combined techniques; only 25 of 234 cases identified were linked to epidural techniques (Zorrilla-Vaca 2018 **Level IV SR**, n=234). Not using surgical masks was the most common association and *staphylococcus aureus* the most common bacterium. Time to onset of meningitis was longer with epidural than spinal techniques (96 h; IQR 84 to 240 vs 24 h; IQR 8 to 72) and mortality rate 13.3%.

5.6.4.4 | Diagnosis and prevention of Infectious complications

Bacterial colonisation of epidural catheter tips is reported to occur in 0 to 28% of patients (Yuan 2008 **Level IV**, n=205; Mishra 2006 **Level IV**, n=466; Steffen 2004 **Level IV**, n=502; Simpson 2000 **Level IV**, n=1,442). The most common organism cultured from the catheter tips was coagulase-negative staphylococcus.

Experimental data suggest that after accidental epidural catheter disconnection, cutting the catheter 2 cm distal to the level of contamination left all such treated catheters sterile, while spray-wipe disinfection or employing ropivacaine 0.75% as flushing solution or a combination of

these measures were not as effective (Scholle 2014 **BS**). The authors suggest spray-wipe disinfection and cutting as the safest strategy.

An *in vitro* comparison of the antibacterial activity of medications used in epidural solutions showed that the minimal inhibitory concentration of bupivacaine for *Staphylococcus aureus*, *Enterococcus faecalis* and *Escherichia coli* was between 0.125% and 0.25% (growth of *Pseudomonas aeruginosa* was not affected at any of the concentrations investigated) (Coghlan 2009 **Level III-2 BS**). Levobupivacaine and ropivacaine showed no activity against *S aureus*, *E faecalis* and *P aeruginosa*, even at the highest concentrations tested, and minimal activity against *E coli* (minimum inhibitory concentrations 0.5 and 1% respectively). The addition of fentanyl, clonidine and adrenaline did not improve antibacterial activity

Chlorhexidine-impregnated dressings of epidural catheters in comparison to placebo or povidone-iodine-impregnated dressings reduced the incidence of catheter colonisation (Ho 2006 **Level I**, 8 RCTs, n=2,588). Chlorhexidine was also the superior skin disinfectant prior to regional catheter insertion with a positive skin culture immediately after skin disinfection of 10% vs 35% of povidone-iodine treated (NNT 4) (Krobbuaban 2011 **Level II**, n=100, JS 4). Chlorhexidine is therefore the recommended skin disinfectant before insertion of regional catheters (Campbell 2014 **GL**). However, chlorhexidine is neurotoxic and skin preparation solutions must be allowed to dry before instrumentation of the epidural space. For this reason, chlorhexidine must also be kept clearly identified and separate from all solutions used for injection. As 2% chlorhexidine is not superior to 0.5% for skin disinfection, UK guidelines recommend the use of 0.5% to reduce neurotoxicity (Campbell 2014 **GL**).

Comprehensive reviews of infectious complications associated with central neuraxial and PNB, including epidemiology, factors affecting bacterial colonisation of the epidural catheter as well as use in febrile, infected and immunocompromised patients are published (Hebl 2011 **NR**; Horlocker 2008 **NR**).

Guidelines for skin antisepsis prior to neuraxial block (Association of Anaesthetists of Great Britain and Ireland, Obstetric Anaesthetists' Association, Regional Anaesthesia UK, Association of Paediatric Anaesthetists of Great Britain and Ireland) recommend thorough handwashing with surgical scrub solution, the use of barrier precautions, including the wearing of a cap, mask, sterile gown and gloves, and of a large sterile drape (Campbell 2014 **GL**). Chlorhexidine in alcohol (0.5%) should be used for skin preparation, but meticulous care must be taken to avoid this reaching epidural space or CSF.

5.6.4.5 | Respiratory depression

The incidence of respiratory depression with epidural opioid analgesia depends on the criteria used to define respiratory depression. In a review of published case series and audit data, the reported incidence of respiratory depression ranged from 1.1% (95% CI 0.6 to 1.9) using respiratory rate to 15.1% (95%CI 5.6 to 34.8) using oxygen saturation (see Section 4.3.1.5 for comments on respiratory rate as an unreliable indicator of respiratory depression); this was very similar to the incidence reported for PCA (Cashman 2004 **Level IV SR**, 165 studies, n≈20,000).

5.6.4.6 | Hypotension

The incidence of hypotension depends on the dose of local anaesthetic and criteria used to define hypotension. In the same review as above, the reported incidence of hypotension was 5.6% (95% CI 3.0 to 10.2) (Cashman 2004 **Level IV SR**, 165 studies, n≈20,000). In the large meta-analysis quoted above, incidence of hypotension is increased by epidural analgesia (OR 4.92; 95%CI 3.11 to 7.78) (Popping 2014 **Level I** [PRISMA], 125 RCTs, n=9,044). Hypotension requiring intervention is increased in another meta-analysis after abdominal surgery (RR 7.13, 95%CI 2.87

to 17.75) (6 RCTs, n=479) (Salicath 2018 **Level I** [Cochrane], 32 RCTs, n=1,716); a subsequent meta-analysis shows an increase in hypotension (RD 0.21; 95% CI 0.09 to 0.33) (17 RCTs, n=870) not leading to increased need for inotropes or vasopressors (RD 0.00; 95%CI -0.06 to 0.07) (23 RCTs, n=1,821) (Guay 2019 **Level I** [Cochrane], 69 RCTs, n=4,680) (significant overlap between all three SRs).

But while TEA was associated with arterial hypotension after thoracic or abdominal surgery, this did not predict inability to walk (Gramigni 2013 **Level IV**, n=161); early mobilisation may be carefully attempted despite hypotension or orthostatic changes.

5.6.4.7 | Treatment failure with epidural analgesia

Epidural analgesia may not always be successful due to a number of factors including catheter malposition or displacement, or technical and patient factors resulting in an inability to achieve effective analgesia (Hermanides 2012 **NR**). Intolerable adverse effects may also be an indication for premature discontinuation. In a large prospective audit, 22% of patients had premature termination of postoperative epidural infusions (Ballantyne 2003 **Level IV**, n=5,628): the most common causes were dislodgement (10%), inadequate analgesia (3.5%) and sensory or motor deficit (2.2%). Most of these failures occurred on or after POD 2. The rate of technical failures in a meta-analysis of epidural analgesia is 6.1% (Popping 2014 **Level I** [PRISMA], 125 RCTs, n=9,044) and risk of failure of the analgesic technique is increased in another meta-analysis (epidural vs IV PCA) (RR 2.48; 95%CI 1.13 to 5.45) (10 RCTs, n=678) (Salicath 2018 **Level I** [Cochrane], 32 RCTs, n=1,716) (siginificant overlap of RCTs). After oesophagectomy, technical failure with TEA occurred in 17 to 22% (Hughes 2018 **Level I** [PRISMA], 3 RCTs, n=93) (0 RCT overlap).

Tunnelling and then suturing the epidural catheter subcutaneously vs fixation with adhesive tape without tunnelling reduced incidence of clinically relevant dislocation of epidural catheters (>20 mm; 1/60 vs 9/61) (Sellmann 2014 **Level II**, n=121, JS 3). Bacterial contamination rates did not differ (8/59 vs 14/54). Length of the catheter in the epidural space may also influence rate of dislocation; in an RCT of 3 vs 5 vs 7 cm insertion, one patient in the 7 cm group had unilateral sensory block and four patients in the 3 cm group had epidural catheter dislodgement (Afshan 2011 **Level II**, n=102, JS 5). The authors suggest that 5 cm is the ideal depth of insertion.

5.6.4.8 | Anastomotic leakage

There has been concern among surgeons about increased risk of anastomotic leakage after bowel surgery due to the stimulating effects of epidural administration of local anaesthetics; so far there is no evidence to support these claims in colorectal surgery. This is supported by a large meta-analysis which shows no difference in the incidence of gastrointestinal anastomotic leakage (RR 0.74, 95%CI 0.41 to 1.32) (17 RCTs, n=848) (Guay 2016b **Level I** [Cochrane], 128 RCTs, n=8,754). An audit of patients undergoing surgery for colorectal cancer in one centre showed that epidural analgesia had no influence on occurrence of anastomotic leakage (Lai 2013 **Level III-2**, n=1,312). After oesophagectomy, TEA reduced the risk of anastomotic leakage (OR 0.13; 95%CI 0.02 to 0.71) (Michelet 2005 **Level III-2**, n=207).

KEY MESSAGES

1. For all types of surgery, epidural analgesia provides better postoperative pain relief compared with parenteral (including PCA) opioid administration (**S**) (**Level I** [Cochrane Review]); except epidural analgesia using a hydrophilic opioid only (**U**) (**Level I**).
2. Thoracic epidural analgesia for open abdominal aortic surgery reduces pain intensity, time to tracheal extubation, time spent in the intensive care unit, rate of acute respiratory failure, myocardial infarction and gastrointestinal bleeding when compared with intravenous opioids (**S**) (**Level I** [Cochrane Review]).
3. High thoracic epidural analgesia used for coronary artery bypass graft surgery reduces postoperative pain, risk of dysrhythmias, pulmonary complications and time to extubation when compared with intravenous opioid analgesia (**Q**) (**Level I** [Cochrane Review]).
4. Thoracic epidural analgesia for thoracotomy reduces the risk of chronic postsurgical pain (**S**) (**Level I** [Cochrane Review]).
5. Thoracic epidural analgesia improves bowel recovery after abdominal surgery (including colorectal surgery) (**S**) (**Level I** [Cochrane Review]).
6. Epidural analgesia is not associated with increased risk of anastomotic leakage after bowel surgery (**S**) (**Level I** [Cochrane Review]).
7. Epidural analgesia provided with local anaesthetics for at least 24 hours compared to systemic opioid analgesia reduces perioperative mortality and multiple morbidities (including ileus, pneumonia, respiratory depression and arrhythmias) but increases hypotension (**U**) (**Level I** [PRISMA]).
8. After laparoscopic colectomy, thoracic epidural analgesia compared to intravenous PCA reduces initial pain scores and time to first bowel opening, but length of hospital stay, total rate of complications (**S**) (**Level I** [PRISMA]), urinary tract infection rates and hospital costs are increased (**U**) (**Level III-2**).
9. Combinations of low concentrations of local anaesthetic agents and opioids for epidural analgesia provide consistently superior pain relief compared with either of the medications alone; epidural opioids alone have no advantage over parenteral opioids (**U**) (**Level I**).
10. Epidural local anaesthetic administration improves oxygenation and reduces pulmonary infections and other pulmonary complications compared with parenteral opioids (**U**) (**Level I**).
11. Chlorhexidine-impregnated dressings of epidural catheters in comparison to placebo- or povidone-iodine-impregnated dressings reduce the incidence of catheter colonisation (**U**) (**Level I**).
12. In patients with multiple rib fractures, thoracic epidural analgesia improves pain relief versus parenteral opioids (**N**) (**Level III-2 SR**), but does not reduce incidence of pneumonia and mortality (**U**) (**Level I**) and may not reduce need for ventilation (**Q**) (**Level III-2 SR**).

13. The combination of thoracic epidural analgesia with local anaesthetics and nutritional support leads to preservation of total body protein after upper abdominal surgery (**U**) (**Level II**).
14. The incidence of permanent neurological damage in association with epidural analgesia is extremely low, especially in the obstetric population, but increases with various comorbidities and risk factors; the incidence is higher where there have been delays in diagnosing an epidural haematoma or abscess (**S**) (**Level IV SR**).
15. Immediate decompression of an epidural haematoma (within 8 hours of the onset of neurological signs) increases the likelihood of partial or good neurological recovery (**S**) (**Level IV SR**).
16. Epidural abscesses present mainly with neurological deficits and back pain; they are best diagnosed with early MRI and best treated with empiric antibiotics (until abscess culture) and immediate surgical decompression when neurological deficits are present (**S**) (**Level IV SR).**

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ The provision of epidural analgesia by continuous infusion, programmed intermittent bolus or patient-controlled administration of local anaesthetic-opioid mixtures is safe on general hospital wards, as long as supervised by an anaesthesia-based pain service with 24-hour medical staff cover and monitored by well-trained nursing staff (**U**).

☑ Prior to insertion of an epidural catheter, thorough handwashing with surgical scrub solution, the use of barrier precautions including the wearing of a cap, mask, sterile gown and gloves and use of chlorhexidine in alcohol for skin preparation are recommended; but meticulous care must be taken to avoid the chlorhexidine solution from reaching epidural space or cerebrospinal fluid (**U**).

5.7 | Intrathecal analgesia

5.7.1 | Medicines used for intrathecal analgesia

5.7.1.1 | Local anaesthetics

IT local anaesthetics provide short-term postoperative analgesia. The use of spinal microcatheters (<24 G) for postoperative infusions of local anaesthetics became controversial when multiple cases of cauda equina syndrome were reported (Bevacqua 2003 **NR**). See also Section 5.7.1.1. above.

5.7.1.2 | Opioids

Morphine is the most frequently studied IT opioid followed by fentanyl (Popping 2012 **Level I** [PRISMA], 65 RCTs, n=3,338; Meylan 2009 **Level I**, 27 RCTs, n=1,205) (0 RCT overlap). Reported IT use of other opioids includes pethidine (meperidine), hydromorphone, diamorphine, pentazocine, sufentanil, tramadol and buprenorphine (Staikou 2014 **Level I**, 105 RCTs, n unspecified). Some clinical studies used very high IT morphine doses (ie 500 mcg or more) without additional benefit. Lower doses (<300 mcg) should be used as there is no clear dose-response relationship with IT morphine for duration of analgesia nor for adverse effects (Popping 2012 **Level I** [PRISMA], 65 RCTs, n=3,338; Meylan 2009 **Level I**, 27 RCTs, n=1,205)

For patients having procedures amenable to spinal anaesthesia alone (orthopaedic, urologic, gynaecologic), the addition of IT morphine (50 mcg to 2 mg) consistently provides an increase in duration of analgesia (as time to first requirement of additional opioid analgesia) (WMD 503 min; 95%CI 315 to 641) vs IT local anaesthetic alone (13 RCTs) (Popping 2012 **Level I** [PRISMA], 65 RCTs, n=3,338). IT fentanyl (10 to 50 mcg) prolongs the duration of analgesia (WMD 114 min; 95%CI 60 to 168). When IT morphine is used, cumulative morphine consumption is reduced (WMD -12 mg; 95%CI -18 to -5) (7 RCTs). There is considerable heterogeneity in the study data and no dose-responsiveness could be identified.

For major abdominal or thoracic surgery, IT opioids are typically combined with a general anaesthetic technique. In patients having abdominal, cardiothoracic or spinal surgery, IT morphine (100 to 500 mcg, without local anaesthetic) reduces pain scores at rest and with movement by 1/10 and 2/10 respectively at both 12 h (7 RCTs, n=353) and 24 h time points (8 RCTs, n=393) (Meylan 2009 **Level I**, 27 RCTs, n=1,205). Morphine-sparing is evident for up to 48 h postoperatively (11 RCTs, n=482), being more pronounced at 24 h after abdominal (5 RCTs, n=272) than cardiothoracic surgery (6 RCTs, n=210).

IT fentanyl is inferior to IT dexmedetomidine which prolongs the pain free period (SMD 2.98; 95%CI 1.69 to 4.27) (7 RCTs, n=491) without increasing the incidence of adverse events including hypotension and bradycardia (8 RCTs each) (Sun 2017 **Level I**, 9 RCTs, n=639).

Lower limb arthroplasty (TKA and THA)

In comparison to IT morphine 100–200 mcg for THA and TKA, local infiltration analgesia (LIA: local anaesthetic, ketorolac 30 mg and adrenaline) results in a small reduction of pain scores at rest and at mobilisation at 24 h, but not at 48 h (Jia 2017 **Level I**, 4 RCTs, n=242). There is no difference in the rescue opioid consumption (4 RCTs) or LOS (3 RCTs). Nausea, vomiting and pruritus are increased in the IT morphine group (4 RCTs).

IT morphine 100–300 mcg vs FNB for TKA shows similar pain scores at 6 h (SMD -0.09; 95%CI -1.62 to 1.43) as well as at 12 h and 24 h, with no difference in morphine consumption for the same time points or PONV (Li 2016 **Level I**, 4 RCTs, n=185). The risk of postoperative pruritus is

reduced with FNB (RD 0.41; 95%CI 0.29 to 0.54). Another overlapping meta-analysis of the same issues shows significant inconsistencies in representing trial results, which makes it difficult to be confident of the conclusions drawn (Tang 2017 **Level I** [PRISMA], 5 RCTs, n=225) (4 RCTs overlap). Thus only the results of the previous meta-analysis are considered (Li 2016 **Level I**, 4 RCTs, n=185).

Several RCTs and studies have shown that the use of low-dose IT morphine has analgesic benefit. One RCT included in both meta-analyses had a third group combining continuous FNB with IT morphine 175 mcg, with no advantage of the combination over the continuous FNB, which was superior to IT morphine alone (Olive 2015 **Level II**, n=81, JS 4). In contrast, a small IT morphine 35 mcg dose improved pain scores when added to a continuous FNB, although the authors noted a higher rate of severe pain in both groups than in comparable studies of FNB (Sundarathiti 2016 **Level II**, n=70, JS 4). For TKA under spinal anaesthesia, where all patients had LIA, addition of IT morphine 100 mcg to adductor canal block [ACB] achieved the lowest pain scores and morphine requirements vs ACB alone and sham ACB (Biswas 2018 **Level II**, n=201, JS 5). However, there was no difference in the primary outcome 'Timed Up and Go (TUG)' test on POD 2 and any other short- or long-term functional outcomes. IT morphine >100–200 mcg in addition to systemic multimodal analgesia for THA and TKA (and a continuous femoral nerve block (FNB) or adductor canal block (ACB) for TKA until POD 1) achieved better analgesia, reduced opioid consumption, better mobilisation and less nausea (Cheah 2018 **Level III-2**, n=598 [467 ITM]). When compared to an US-guided fascia iliaca block for THA under spinal anaesthesia, IT morphine 100 mcg reduced the cumulative morphine consumption at 48 h and time to mobilisation (by 2 h) without a significant difference in adverse side effects (Kearns 2016 **Level II**, n=108, JS 5). Compared to a continuous lumbar plexus catheter technique for THA, IT morphine 100 mcg added to spinal anaesthesia resulted in similar pain scores and opioid supplementation rates, but higher rates of pruritus (Fredrickson 2015 **Level II**, n=50, JS 2).

Caesarean section

IT opioids have been used as a component of the spinal anaesthetic for Caesarean section for many years. The addition of IT morphine 50–250 mcg increases the median time to first analgesia from 2 h (range 1 to 4 h) to 27 h (range 11 to 29 h) (Dahl 1999 **Level I**, 15 RCTs, n=535). Higher doses of IT morphine (>100–250 mcg) vs lower doses (50–100 mcg) for analgesia after Caesarean section lead to a longer time to first analgesic request (MD 4.49 h; 95%CI 1.85 to 7.13), but with no significant difference in pain scores or morphine consumption (Sultan 2016 **Level I**, 11 RCTs, n=480) (3 RCTs overlap). The high-dose IT morphine group has higher incidence of PONV and pruritus (NNH 5.9; 95%CI 3.4 to 20.0) with no effect on Apgar scores.

IT morphine in a dose of 50 mcg had similar analgesic effects to 100 and 150 mcg when used with a spinal block and ketorolac with a similar side effect profile (with the lowest dose having a slightly reduced incidence of pruritus) (Berger 2016 **Level II**, n=144, JS 5). IT morphine 50 mcg had similar analgesic effects to 100 mcg, but the higher dose resulted in a significantly higher rate of pruritus (64 vs 40%) (Mikuni 2010 **Level II**, n=75, JS 3). Using an up–down sequential allocation the ED_{90} was determined to be 75 mcg (95%CI 46 to 93) for IT hydromorphone and 150 mcg (95%CI 145 to 185) for IT morphine with no difference between both for analgesia, side effects and patient satisfaction (Sviggum 2016 **Level II**, n=80, JS 5).

IT fentanyl 12.5 to 50 mcg added to spinal anaesthesia leads to a longer time to first analgesic request (MD 91 min; 95%CI 69 to 113) (12 RCTs, n=574) and reduces the incidence of nausea/vomiting (RR 0.41; 95%CI 0.24 to 0.70) (NNT 6.5) (12 RCTs, n=580), but increases the incidence of intraoperative pruritus (RR 5.89; 95%CI 2.07 to 16.79) (NNH 13.5) (13 RCTs, n=604) (Uppal 2020 **Level I** [PRISMA], 17 RCTs, n=1,064).

IT fentanyl 25 mcg/morphine 100 mcg combination vs morphine alone improved intraoperative analgesia and did not affect 24 h postop opioid requirements, but increased 12 h opioid requirements and PONV rates (Weigl 2017 **Level II**, n=60, JS 5).

Compared to a transversus abdominus plane (TAP) block, IT morphine 100 mcg resulted in lower pain scores, but only at 10 h, while causing more PONV and pruritus (Loane 2012 **Level II**, n=66, JS 5). This study failed to achieve full recruitment. IT morphine 100 mcg vs ropivacaine 0.2% via wound catheter had the same efficacy with no difference in median time to first morphine request (Lalmand 2017 **Level II**, n=192, JS 5). Both techniques were superior to the control group with spinal anaesthesia by bupivacaine/sufentanil only.

Labour

Adding IT morphine 50 to 250 mcg to single-injection IT bupivacaine/fentanyl 12.5 or 25 mcg or bupivacaine/sufentanil 5 or 10 mcg prolongs pain relief during labour by 61 min (range 3 to 155 min) with no effect on SMD of pain intensity (Al-Kazwini 2016 **Level I** [PRISMA], 5 RCTs, n=286).

Spinal surgery

IT morphine (100 mcg to 1 mg; 3.5–20 mcg/kg) vs placebo (6 RCTs) or control after spinal surgery results in reduced pain scores (7 RCTs) and postoperative opioid consumption (8 RCTs) during the first 24 h postoperatively with a higher rate of pruritus; respiratory depression only occurred in the IT morphine group (6/231) (8 RCTs) (Pendi 2017 **Level I**, 8 RCTs, n=393). This review includes abstract data for a later peer reviewed publication (Yen 2015 **Level II**, n=32, JS 4).

Cardiothoracic surgery

IT morphine 7 mcg/kg prior to surgical aortic valve surgery had a better analgesic effect postoperatively vs titrated systemic fentanyl, with reduced parenteral opioid requirements and increased time to first opioid rescue (Elgendy 2017 **Level II**, n=44, JS 5). In addition, the IT morphine group had a slightly earlier extubation and shorter ICU LOS. There were no reports of increased side effects. In minimally invasive cardiac surgery, IT morphine 1.5 mcg/kg reduced PCA-opioid requirements and pain scores (Mukherjee 2012 **Level II**, n=62, JS 3). For open thoracotomy procedures, the combination of IT morphine 4 to 5 mcg/kg (max 500 mcg) and sufentanil 0.2−0.3 mcg/kg (max 25 mcg) with a continuous PVB offered slightly higher but acceptable pain scores vs epidural analgesia (Dango 2013 **Level II**, n=84, JS 4).

Hepatic surgery

After liver resection, IT morphine 500 mcg/fentanyl 150 mcg resulted in better analgesia and lower opioid requirements than morphine PCA up to 18 h postoperatively (Roy 2006 **Level II**, n=20, JS 3). IT morphine 200 mcg vs epidural analgesia in liver resections showed comparable pain scores, although epidural recipients had lower opioid consumption and intubation duration (De Pietri 2006 **Level II**, n=50, JS 2). Similarly, in patients for liver resections, IT morphine 500 mcg and fentanyl 15 mcg was inferior to epidural bupivacaine infusion, with twice as much morphine consumption (123 mg vs 59 mg) and more pain (Mondor 2010 **Level II**, n=44, JS 5).

Urological surgery

IT morphine 50 to 200 mcg (± clonidine) after prostatic surgery resulted in better analgesia and lower opioid requirements vs morphine PCA up to 18 h postoperatively (Brown 2004 **Level II**, n=99, JS 5). For transurethral resection of the prostate under spinal anaesthesia, low-dose IT morphine 25 and 50 mcg resulted in similar pain scores for up to 24 h, but the higher-dose group had more pruritus (15 vs 0%) (Duman 2010 **Level II**, n=70, JS 4).

Other surgery

IT hydromorphone 5 or 10 mcg in addition to spinal anaesthesia for knee arthroscopic surgery reduced pain scores for up to 12 h vs 2.5 mcg dose or placebo (Lee 2012 **Level II**, n=60, JS 3). Nausea was more frequent (46%) in the 10 mcg group.

After open nephrectomy, IT morphine 330 mcg plus IV PCA versus IV PCA alone resulted in better analgesia and reduced systemic opioid requirements with similar adverse effects except for increased pruritus (77 vs 26%) (Kim 2016 **Level II**, n=45, JS 4).

IT morphine at three different doses (100, 200 and 300 mcg) for abdominal hysterectomy was superior to placebo for analgesia up to 24 h, with the 200 mcg dose equivalent to 300 mcg and superior to 100 mcg in rescue analgesia requirements (Hein 2012 **Level II**, n=144, JS 5). For inguinal hernia repair, IT morphine 100 mcg had similar analgesia to 400 mcg with increased PONV in the higher dose group (Meco 2016 **Level II**, n=48, JS 4).

For endovenous laser ablation in lower extremity venous insufficiency/varicose vein disease, the addition of IT morphine 100 mcg versus IT fentanyl 25 mcg to bupivacaine spinal anaesthesia reduced shivering vs placebo control as well as increased time to first analgesia use similarly (Onk 2016 **Level II**, n=90, JS 4).

5.7.1.3 | Adverse effects

Typical adverse effects of IT opioids include nausea and vomiting, pruritus and delayed respiratory depression (Popping 2012 **Level I** [PRISMA], 65 RCTs, n=3,338; Meylan 2009 **Level I**, 27 RCTs, n=1,205) (0 RCT overlap).

Opioid-induced ventilatory impairment

The definition of respiratory depression in different investigations often lacks uniformity, with many studies using respiratory rate as the primary marker and others using desaturation to different levels and a few others using the need for opioid antagonists. This significantly compromises interpretation of reported event rates. OIVI is a more appropriate term (Macintyre 2011 **NR**). Patients may be hypoxic or hypercapnic with a normal respiratory rate (Bailey 1993 **Level IV EH**, n=20), while others may be able to maintain normocarbia with a lower respiratory rate (Boezaart 1999 **Level II**, n=60, JS 5). In a volunteer study, clinical signs or symptoms including respiratory rate, sedation and pupil size did not reliably indicate hypoventilation or hypoxaemia, unlike peripheral pulse oximetry (Bailey 1993 **Level IV EH**, n=20); although desaturation itself is a late indicator when supplemental oxygen is being administered (Shapiro 2005 **Level IV**, n=1,524). Very large numbers of patient exposures are needed to adequately quantify risk of infrequent events (eg OIVI), thus most studies and meta-analyses will have a limited capacity to report meaningfully on such adverse effects (see also Section 4.3.1.4).

When measured in opioid-naïve volunteers, respiratory depression peaked at 3.5 to 7.5 h following IT morphine at 200 to 600 mcg doses (Bailey 1993 **Level IV EH**, n=20). Volunteers given 600 mcg had significant depression of the ventilatory response to CO_2 up to 19.5 h later.

In patients following major surgery, a 7.6% incidence of respiratory depression was reported for IT morphine >300 mcg vs IV PCA morphine (OR 7.86; 95%CI 1.54 to 40.3) (3 RCTs, n=172) (Meylan 2009 **Level I**, 27 RCTs, n=1,205). In patients having spinal surgery, IT morphine only resulted in respiratory depression (6/231) vs placebo (0/162) (RR 3.48; 95%CI 0.41 to 29.32) (Pendi 2017 **Level I**, 8 RCTs, n=393). In patients having minor surgery, major respiratory depression (endpoint "*SpO2 85 to 90%*" in addition to respiratory rate <12) occurred in 3 of 290 (1.0%) patients receiving IT bupivacaine alone and 15 of 410 (3.7%) receiving IT bupivacaine/morphine (OR 3.49; 95%CI 1.25 to 9.73) (Popping 2012 **Level I** [PRISMA], 65 RCTs, n=3,338). In the same analysis, the incidence of OIVI in patients receiving IT fentanyl (0.4%) was no different to control (0%). Thus,

indirect comparisons suggest that the risk of OIVI is more pronounced with IT morphine than with IT fentanyl.

A meta-analysis for a range of procedures, comparing IT morphine doses of <300 mcg, ≥300 mcg and placebo reported a greater risk of respiratory depression (respiratory rate <8 to 12) with the higher doses (9%) with no increased risk with lower morphine dose (1%) vs systemic opioids (2%) (Gehling 2009a **Level I**, 28 RCTs, n=1,414). This difference was not statistically significant but this may reflect the relatively small number of patients in the higher dose group (n=87). The incidence of pruritus was increased for all doses (low dose RR 1.8; 95%CI 1.4 to 2.2 vs high dose RR 5.0; 95%CI 2.9 to 8.6); the risk of nausea and vomiting was increased only in those patients given <300 mcg morphine.

For Caesarean section, when IT opioids (all types of opioids and all doses) were combined with local anaesthetic for analgesia, the rate of respiratory depression was low and not significantly different from controls (Dahl 1999 **Level I**, 15 RCTs, n=535). In a large case series, clinically detected respiratory depression in the 24 h following IT morphine 150 mcg was noted in 0.26% of patients (Kato 2008 **Level IV**, n=1,915). In a closed claims study from the USA, a maternal death from IT opioid overdose is reported (Clayton 2018 **CR**).

A prospective audit of IT morphine 200–800 mcg for pain relief following a range of surgical procedures reported a high degree of patient satisfaction and effective analgesia in the first 24 h (Gwirtz 1999 **Level IV**, n=5,969). The incidence of pruritus was 37%, nausea and vomiting 25% and respiratory depression 3% ($PaCO_2$ >50 mmHg and/or respiratory rate <8).

Overall, considering the increased risk of OIVI with IT morphine, the lowest effective dose of IT opioid should be used and surveillance for OIVI should continue for at least 18 to 24 h following a single dose (Bailey 1993 **Level IV**; Bujedo 2012 **NR**). A current ASA guideline recommends a minimum monitoring period of 24 h after administration of single-injection IT morphine, with monitoring of at least once per hour for the first 12 h and then at least once every 2 h for the next 12 h (ASA 2016 **GL**). The monitoring should consist of level of consciousness, adequacy of ventilation (rate and depth of respiration) and pulse oximetry. Higher risk patients may require additional monitoring and for a longer period of time. This document also discusses in further detail identification of at-risk patients and strategies for prevention, detection and management of OIVI in patients with neuraxial opioids.

A similar guideline has been published by the Society for Obstetric Anesthesia and Perinatology (SOAP) for the use of neuraxial opioids in Caesarean section patients (Bauchat 2019 **GL**).

Pruritus

Pruritus is a frequent adverse effect of opioids by all routes. The rate following IT morphine is higher than that for patients receiving IV PCA morphine (OR 3.85; 95%CI 2.40 to 6.15) (Meylan 2009 **Level I**, 27 RCTs, n=1,205) and is dose-dependent (Sultan 2016 **Level I**, 11 RCTs, n=480). The itch is thought to be caused by stimulation of spinal and supraspinal mu-opioid receptors which includes the trigeminal nucleus and explains the frequency of facial itch (Kumar 2013 **NR**). The incidence of pruritus with IT morphine 50 mcg to 1 mg was 29.2% vs 4.4% with bupivacaine alone (OR 6.92; 95%CI 4.51 to 10.6; NNH 4) (17 RCTs) (Popping 2012 **Level I** [PRISMA], 65 RCTs, n=3,338). IT fentanyl 10–40 mcg had an incidence of pruritus of 27.3% vs 0% with bupivacaine alone (13 RCTs).

Incidence following IT opioids for Caesarean section

Pregnant women report greater rates of pruritus of 60 to 100%, which may be due to an interaction of oestrogen with opioid receptors (Kumar 2013 **NR**). While the incidence of pruritus is consistently high, the number requiring treatment is lower; in post-Caesarean section patients receiving 100 mcg IT morphine, 64% of patients reported pruritus with the proportion requiring treatment being 18% (Mikuni 2010 **Level II**, n=75, JS 3). In patients having Caesarean section under spinal anaesthesia, IT morphine 100 mcg was vs oral opioid (oxycodone CR), the IT morphine

group had similar overall pain scores but reported better satisfaction at 24 h and fewer high pain scores but experienced more pruritus (87 vs 56%) (McDonnell 2010 **Level II**, n=111, JS 5).

5HT$_3$-receptor antagonists

There may be a connection between serotonin (5-HT) levels and pruritus, as IT morphine increases serotonin plasma concentrations in a dose-dependent fashion by 283% (10 mcg) vs 556% (200 mcg), with pruritus rates of 55% and 75% respectively (Aly 2018 **Level II**, n=40, JS 5). 5HT$_3$-receptor antagonists decrease the incidence of pruritus related to IT opioids with an NNT of 6 (OR 0.44; 95%CI 0.29 to 0.68) (Bonnet 2008 **Level I**, 15 RCTs, n=1,337). This analysis included a high number of Caesarean section patients, who reported higher rates of pruritus. In a subgroup analysis, the antipruritic effect is seen in the morphine (9 RCTs) but not fentanyl/sufentanil recipients (5 & 1 RCTs). A similar analysis based purely on Caesarean section patients receiving IT morphine does not identify a decrease in incidence in pruritus overall with prophylactic 5HT$_3$ antagonists, but use does reduce the incidence of severe pruritus with an NNT of 3 for established pruritus (George 2009 **Level I** [PRISMA], 9 RCTs, n=1,152) (6 RCTs overlap with Bonnet 2008). Ondansetron 4 to 8 mg reduces pruritus after IT morphine in non-obstetric cases (RR 0.63; 95%CI 0.45 to 0.89) (7 RCTs [1 RCT epidural morphine], n=576) (Wang 2017 **Level I** (PRISMA), 10 RCTs, n=811). However, the result for Caesarean section was not significant with a high degree of heterogeneity (3 RCTs, n=253). Reasons for an inconclusive result in the obstetric group highlighted by the authors include the co-administration of a lipid soluble opioid fentanyl, the delay in administration of ondansetron until after IT morphine because of concerns of placental transfer and altered pharmacokinetic handling of ondansetron in parturient women. Specifically, in pruritus caused by IT fentanyl 10 to 25 mcg and IT sufentanil 10 mcg, IV ondansetron 8 mg does not reduce the incidence of pruritus, but does reduce the need for rescue medication (RR 0.57; 95%CI 0.35 to 0.91) (Prin 2016 **Level I**, 6 RCTs, n=555).

Opioid antagonists

There is limited data and conflicting results regarding the use of opioid antagonists in treating pruritus following IT opioids. However, with parenteral opioids, overall IV naloxone reduces the incidence of pruritus (OR 0.40; 95%CI 0.21 to 0.79) and nausea (OR 0.62; 95%CI 0.43 to 0.89) but not vomiting (Murphy 2011 **Level I**, 8 RCTs, n=800). Other methods that have been described for prevention include nalbuphine (Tubog 2019 **Level I** [PRISMA}, 17 RCTs, n=1,052), mirtazapine (a noradrenergic and specific serotonergic antidepressant [NaSSA]) and dopamine antagonists such as droperidol (Kumar 2013 **NR**). SC methylnaltrexone 12 mg (a mu-opioid receptor antagonist that works peripherally and does not cross the blood brain barrier) reduced nausea, but had no effect on pruritus or urinary retention (Zand 2015 **Level II**, n=72, JS 5). Similarly, SC methylnaltrexone 12 mg versus placebo did not reduce pruritus from IT morphine 100 mcg after Caesarean section (84% vs 88%) (Paech 2015 **Level II**, n=37, JS 5).

Other treatments

Other treatments for established pruritus include pentazocine (a mixed opioid agonist-antagonist with kappa receptor effects) which was more effective in treating pruritus post Caesarean section than ondansetron 4 mg (Tamdee 2009 **Level II**, n=208, JS 5). IV pentazocine 15 mg had a prophylactic effect on pruritus after IT opioids for Caesarean section vs placebo (RR 0.69; 95%CI 0.52 to 0.90) (Hirabayashi 2017 **Level II**, n=122, JS 5). Diphenhydramine 25 mg has also been reported to be as effective as ondansetron 4 mg (Siddik-Sayyid 2010 **Level II**, n=113, JS 5).

Preoperative acupuncture vs sham acupuncture maintained for 48 h postoperatively was ineffective in reducing pruritus caused by IT morphine for Caesarean section (Mazda 2018 **Level II**, n=30, JS 5).

Nausea and vomiting

Postoperative nausea is common after IT morphine, especially in obstetrics. Consensus guidelines exist for PONV management; however, these do not address IT opioids specifically (Gan 2014 **GL**). Following minor surgical procedures, the addition of IT morphine significantly increased the risk of nausea from 29.4% to 39.4% (OR 1.66; 95%CI 1.05 to 2.64) (NNH 9.8) (10 RCTs, n=361) and vomiting from 16.6% to 26.2% (OR 1.88; 95%CI 1.20 to 2.94) (NNH 10) (14 RCTs, n=505) vs IT local anaesthetic with systemic analgesics (Popping 2012 **Level I** [PRISMA], 65 RCTs, n=3,338). Following major surgery, comparing IT opioids to systemic opioids there was a nonsignificant increase in the incidence of nausea (30.5 vs 24.2%; OR 1.22; 95%CI 0.77 to 1.95) and no difference in the incidence of vomiting (23.8 vs 22.6%; OR 1.05; 95%CI 0.63 to 1.73) (Meylan 2009 **Level I**, 27 RCTs, n=1,205). A low dose of IT morphine 100 mcg caused no vomiting vs 400 mcg (23%) for inguinal hernia repair (Meco 2016 **Level II**, n=48, JS 4).

Following Caesarean section with IT morphine and fentanyl, ondansetron and transdermal scopolamine were equally effective in reducing emesis from 59.3% (control) to 41.8% (ondansetron) and 40% (scopolamine), although scopolamine use was associated with more anticholinergic adverse effects (Harnett 2007 **Level II**, n=240, JS 4). The combination of ondansetron with either dexamethasone or droperidol had a better antiemetic effect after gynaecological surgery with IT morphine vs droperidol/dexamethasone (Sanchez-Ledesma 2002 **Level II,** n=90, JS 4), although this latter combination was superior vs either alone (Wu 2007 **Level II**, n=120, JS 5).

Urinary retention

The incidence of urinary retention is not increased in patients receiving IT morphine for major surgery (Gehling 2009b **Level I**, 28 RCTs, n=1,414; Meylan 2009 **Level I**, 27 RCTs, n=1,205); however, in patients having spinal anaesthesia for minor surgery, IT morphine increases the risk of urinary retention (OR 3.9; 95%CI 1.94 to 7.86) (NNH 6.5) (7 RCTs, n=225) (Popping 2012 **Level I** [PRISMA], 65 RCTs, n=3,338).

Other adverse effects

In women in labour, reactivation of oral herpes simplex labialis was more frequent following IT morphine for labour analgesia than IV PCA morphine (38 vs 16.6%) (Davies 2005 **Level II**, n=98, JS 4).

Cardiovascular effects of IT opioids have generally not been reported. In a retrospective cohort study, IT hydromorphone 50 to 80mcg used in patients having elective colorectal resection with restricted fluid therapy found a higher rate of hypotension (mean arterial blood pressure <60 mmHg or systolic blood pressure <110 mmHg) in those receiving hydromorphone (4.3%) vs the control group up to 12 h (Hubner 2013 **Level III-2**, n=163). This normalised by 24 h and was not associated with any identified adverse outcomes. IT morphine 7 mcg/kg in surgical aortic valve replacement decreased mean arterial pressure and heart rate while preserving cardiac output, pulmonary capillary wedge pressure and central venous pressure (Elgendy 2017 **Level II**, n=44, JS 5).

Caution has been advised regarding the use of IT opioids in patients who are at risk of spinal cord ischaemia (eg thoracic aortic stenting/surgery) (Fedorow 2010 **NR**), although its use has been described (Chaney 1996 **Level IV**). Such caution is based primarily on laboratory data, although a case report is published (Kakinohana 2003 **CR**).

5.7.1.4 | Adjuvant medicines

A variety of adjuvant medicines have been used with IT analgesia, including clonidine, dexmedetomidine, ketamine, neostigmine and midazolam. Many medicines are not licensed for use as spinal analgesic agents; however adequate evidence from the literature may make their use acceptable (for more detail see Chapter 4).

Clonidine and Dexmedetomidine

The addition of clonidine 30 to 150 mcg to IT morphine 100 to 500 mcg causes a small increase in analgesia duration (1.63 h; 95%CI 0.93 to 2.33) (5 RCTs, n=464) and reduces the amount of systemic morphine consumption over 24 h (4.45 mg; 95%CI 1.40 to 7.49) (7 RCTs, n=629) (Engelman 2013 **Level I** [PRISMA], 7 RCTs, n=503). Incidence of hypotension was also increased (OR 1.78; 95%CI 1.02 to 3.12).

For major abdominal cancer surgery, IT dexmedetomidine 5 mcg added to IT morphine 500 mcg and bupivacaine did not improve analgesia vs the IT morphine/bupivacaine group (Abdel-Ghaffar 2016 **Level II**, n=90, JS 5). Both groups with adjuvants experienced better analgesia than bupivacaine alone.

Magnesium

Magnesium most likely contributes to analgesia by acting as a noncompetitive NMDA-receptor antagonist in the spinal cord. There was no benefit with IT versus intraperitoneal magnesium in animal experiments (Messeha 2016 **BS**). Magnesium 1.67–50% with opioid with or without local anaesthetic prolongs the time to first analgesia requirement in non-obstetric populations (SMD 1.38; 95%CI 0.6 to 2.11) but not obstetric patients (Morrison 2013 **Level I**, 15 RCTs, n=980). This may be an effect of fewer studies in the obstetric group. There is no increase in incidence of hypotension. There was a high degree of heterogeneity making any firm conclusion difficult.

KEY MESSAGES

1. Intrathecal morphine improves analgesia and is opioid-sparing for up to 24 hours after major surgery including abdominal (**S**), orthopaedic (**N**), spinal (**N**) (**Level I** [PRISMA]) and cardiothoracic surgery (**N**) (**Level II**).
2. Adding intrathecal morphine to intrathecal bupivacaine/fentanyl or intrathecal bupivacaine/sufentanil prolongs pain relief after labour (**N**) (**Level I** [PRISMA]).
3. The addition of intrathecal fentanyl (**N**) (**Level I** [PRISMA]) and morphine to spinal anaesthesia prolongs time to first analgesic request after Caesarean section (**N**) (**Level I**).
4. Intrathecal morphine in comparison to peripheral regional analgesia techniques offers similar analgesic benefits, but increases adverse effects (nausea, vomiting, pruritus) after lower limb arthroplasty (**N**) (**Level I**).
5. The incidence of opioid-induced ventilatory impairment, pruritus and postoperative nausea and vomiting is higher with intrathecal morphine compared with intravenous PCA opioids (**S**) (**Level I**).
6. Pruritus with intrathecal opioids is dose-dependent (**N**) (**Level I**) and can be effectively prevented and treated with $5HT_3$ antagonists in non-obstetric patients, but only treated but not prevented in obstetric patients (**Q**) (**Level I**)
7. The addition of intrathecal magnesium to opioids and/or local anaesthetics results in slightly longer analgesia in non-obstetric patients (**U**) (**Level I**).
8. The addition of intrathecal clonidine to intrathecal morphine results in slightly longer analgesia and reduced opioid requirements (**U**) (**Level I**).
9. Pruritus with intrathecal opioids cannot be treated with methylnaltrexone (**N**) (**Level II**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ The absence of consistent dose-responsiveness to the efficacy of intrathecal opioids and the increase in adverse effects with higher doses suggests that the lowest effective dose (typically 50-200 mcg morphine) should be used (**Q**).

☑ Patients receiving intrathecal opioids should be monitored for opioid-induced ventilatory impairment for the anticipated duration of opioid effects, eg 18 to 24 hours after intrathecal morphine (**S**).

☑ Clinical experience with morphine, fentanyl and sufentanil has shown no neurotoxicity or behavioural changes at normal clinical intrathecal doses (**U**), however caution is recommended in patients who are at risk of spinal cord ischaemia (**U**).

5.8 | Other regional and local analgesic techniques

Regional and local analgesic techniques have evolved recently, with a large number of new ultrasound-guided blocks. There have been developments in our understanding of anatomy and proof-of-concept studies on neuromodulation for acute pain management. Regional and local analgesic techniques should be used in conjunction with oral multimodal analgesic techniques.

Adjuvant agents to local anaesthetics are considered in other sections: eg alpha-2-agonists in Section 4.9.2 and corticosteroids in Section 4.12.2 and opioids in Section 4.2.3.

5.8.1 | Needle and catheter localising techniques

Techniques used to precisely identify correct needle location and hence local anaesthetic and catheter placement include anatomic landmarks, peripheral nerve stimulation (PNS) and ultrasound (US) guidance. Radiologic imaging and direct vision during surgery have also been used. In comparison with PNS, blocks performed using US-guidance are more likely to be successful (RR 0.41 [for block failure]; 95%CI 0.26 to 0.66) (9 RCTs), faster to perform (WMD -1.1 min less to perform with US; 95%CI -1.7 to -0.4) (7 RCTs), have faster onset (29% shorter onset time; 95%CI 45 to 12%) (8 RCTs), longer duration (SMD 25%; 95%CI 12 to 38) (5 RCTs) and reduced vascular puncture (RR 0.16; 95%CI 0.05 to 0.47) (4 RCTs) (Abrahams 2009 **Level I**, 13 RCTs, n=941). US-guidance is associated with an increase in success rate of nerve blocks vs all non-US techniques (RR 1.11; 95%CI 1.06 to 1.17) and vs PNS alone (RR 1.11; 95%CI 1.05 to 1.17) (Gelfand 2011 **Level I**, 16 RCTs, n=1,264) (8 RCTs overlap with Abrahams 2009). US-guided techniques vs PNS (17 RCTs) and other needle-localisation techniques (2 RCTs) are associated with higher success rates, faster onset of block and lower vascular puncture rate (McCartney 2010 **Level I**, 25 RCTs, n=2,187) (8 RCTs overlap with Abrahams 2009 & 9 RCTs overlap with Gelfand 2011).

These findings are also confirmed for placement of catheters, where US- vs PNS-guidance results in a higher success rate (9 RCTs, n=530) and a lower rate of accidental vascular puncture (RR 0.13; 95% CI: 0.04 to 0.38) (15 RCTs) vs PNS guidance (Schnabel 2013 **Level I** [PRISMA], 15 RCTs, n=977). Stimulating catheters have been compared with nonstimulating catheter techniques in establishing continuous FNBs for postoperative analgesia following TKA. There was no difference in quality of postoperative analgesia between these two insertion techniques (Barrington 2008 **Level II**, n=82, JS 5; Morin 2005 **Level II**, n=141, JS 3). Stimulating catheters have also been compared with nonstimulating catheter techniques at other anatomical locations with inconclusive results (Stevens 2007 **Level II**, n=43, JS 4; Dauri 2007 **Level II**, n=70, JS 3; Rodriguez 2006 **Level II**, n=48, JS 3).

US-guidance has been compared with stimulating and non-stimulating techniques for continuous infraclavicular brachial plexus block. The combination of US- and PNS-guidance (with stimulating catheters) resulted in the highest primary success and reduced secondary catheter failure (McCartney 2010 **Level I**, 1 RCT: Dhir 2008 **Level II**, n=66, JS 3). In the placement of popliteal sciatic nerve catheters, US-guidance alone resulted in similar analgesic outcomes for up to 48 h vs US- and PNS-(stimulating catheter) guidance (Robards 2013 **Level II**, n=21, JS 3). In patients having TKA, the combination of US-guidance and PNS (needle and/or stimulating catheter) was not different to US-guidance alone in analgesic efficacy over 48 h (Farag 2014 **Level II**, n=437, JS 4); stimulating catheter use was associated with a longer procedural time.

An analysis of the German Network of Regional Anaesthesia database between 2007 and 2012 reveals the effects of being awake (n=25,004), sedated (n=15.121) or anaesthetised (n=2,529) on complications of regional anaesthesia (Kubulus 2016 **Level III-2**, n=42,654). There are no differences in the rates of LAST or pneumothorax. For peripheral nerve blocks, both sedation (aOR 1.82; 95%CI 1.50 to 2.21) and general anaesthesia (aOR 1.33; 95%CI 1.01 to 1.78) are

associated with an increased risk of a bloody tap. The risk for multiple skin puncture is lower in sedated (aOR 0.78; 95%CI 0.71 to 0.85) and higher in anaesthetised patients (aOR 1.28; 95%CI 1.12 to 1.46).

5.8.2 | Continuous and single-injection peripheral nerve blocks

Percutaneous perineural catheter placement enables an infusion of local anaesthetic increasing the duration of analgesia and associated benefits. Continuous peripheral nerve blockade (CPNB) is indicated for treatment of acute postoperative pain, vascular insufficiency, chronic pain conditions and cancer-related pain. CPNB is used in hospital, ambulatory and in trauma settings (Ilfeld 2017a **NR**; Ilfeld 2011a **NR**).

5.8.2.1 | Continuous peripheral nerve block compared to single-injection techniques

Compared with single-injection techniques, CPNB improve pain control, decrease opioid requirements, reduce nausea and improve patient satisfaction postoperatively (Bingham 2012 **Level I**, 21 RCTs, n=702). CPNBs after ambulatory upper and lower limb surgery vs single-injection blocks reduce pain at rest (5 RCTs) and during movement (in 4 of 5 RCTs) and opioid requirements for the first 24 h (1 RCT), but not consistently sustained beyond this time frame (Saporito 2017 **Level I** [PRISMA], 5 RCTs, n=160); the quality and size of the RCTs included limits these statements. These findings are consistent with some but not all recent studies.

Following TKA, various analgesic modalities have been compared:

- There were no differences between continuous FNB, single-injection FNB and LIA by surgeon in pain scores on the morning of POD 2 (primary outcome) or 48 h opioid consumption (Choi 2016 **Level II**, n=120, JS 5). However, both continuous FNB and LIA resulted in superior pain control vs the single-injection group on POD 1;
- There were no differences between continuous FNB infusion of ropivacaine 0.2%, ropivacaine 0.1% vs placebo (sodium chloride 0.9 %) for the primary outcome 'time to discharge readiness' (Albrecht 2014 **Level II**, n=99, JS 5). This RCT was terminated early because of changes in institutional pathways;
- Continuous FNB was not superior (pain scores at 48 h) to single-injection FNB with no difference in opioid consumption and functional recovery (Dixit 2018 **Level II**, n=85, JS 4).
- Single-injection ACB (combined with sciatic nerve block and posterior capsule LIA by surgeon) provided comparable early analgesia for 32 h vs continuous ACB, but continuous ACB improved pain scores beyond 42 h (Turner 2018 **Level II**, n=60, JS 5). The local anaesthetic adjuvants included clonidine 33.4 mcg, buprenorphine 150 mcg, dexamethasone 2 mg, and adrenaline;
- Single-injection ACB ropivacaine 0.5% 20 mL vs ropivacaine/IV dexamethasone 8 mg similarly reduced 24 h opioid consumption vs continuous ACB (ropivacaine 0.5% 20 mL then 0.2% 5 mL/h for 48 h) where all patients received periarticular infiltration with ropivacaine 0.5% 30 mL at surgery (Lee 2018, **Level II**, n=180, JS 3). Possible reasons for superiority over catheter technique include catheter migration or poor placement and superior injectate spread of the single-injection technique.

5.8.3 | Upper limb blocks

5.8.3.1 | Interscalene and suprascapular nerve block

Compared with a single-injection interscalene block, continuous interscalene block with ropivacaine 0.2% following shoulder surgery (rotator cuff surgery, arthroplasty) improved pain outcomes, sleep, patient satisfaction, time to discharge readiness and achieved a greater degree of shoulder movement (Salviz 2013 **Level II**, n=71, JS 3; Yang 2013 **Level II**, n=56, JS 4; Mariano 2009

Level II, n=32, JS 5; Ilfeld 2006 **Level II**, n=32, JS 3). Because of close proximity to the neuraxis, a test dose of local anaesthetic through an interscalene catheter should precede a continuous infusion. Performing interscalene blockade in adults under general anaesthesia is controversial with case reports of block-related mechanical injury to the spinal cord (Benumof 2000 **CR**). Phrenic nerve block is the most common adverse effect of interscalene block. Strategies to reduce the likelihood or magnitude of phrenic nerve block include reducing local anaesthetic dose, using US-guidance, injecting at the C7 vertebral level and use of suprascapular or axillary block (Verelst 2013 **NR**). Suprascapular block resulted in reduced pain vs placebo or subacromial local anaesthetic infusion (Jeske 2011 **Level II**, n=45, JS 4). For shoulder arthroscopy, interscalene block vs combined suprascapular and axillary block resulted in superior analgesia in PACU, but inferior analgesia at 24 h (Dhir 2016 **Level II,** n=60, JS 5). Suprascapular nerve block (anterior approach deep to omohyoid muscle) was compared with interscalene block for shoulder arthroscopy using a composite outcome of pain and grip strength (Wiegel 2017 **Level II,** n=336, JS 5). Different ropivacaine dose used in the two study groups (interscalene 150 mg vs suprascapular 100 mg) resulted in reduced motor block with the suprascapular block and non-inferiority for pain outcomes. Following shoulder arthroplasty, vital capacity at 24 h (primary outcome) was reduced more with continuous interscalene (by 991 mL) vs supraclavicular (by 803 mL) block (Auyong 2017 **Level II,** n=75, JS 5). However, anterior suprascapular block had the least effect on vital capacity (reduced by 464 mL) indicating a potential advantage in using this approach in patients with pulmonary disease, while there were no differences in analgesic outcomes.

5.8.3.2 | Other brachial plexus blocks

For surgery in the area of the forearm, infraclavicular block offers advantages due to a lower likelihood of tourniquet pain during surgery, more reliable blockade of the musculocutaneous nerve when compared to a single-injection axillary block, and a significantly shorter block performance time compared to multi-injection axillary and mid-humeral blocks (Chin 2013 **Level I** [Cochrane], 22 RCTs, n=1,732). The incidence of insensate limb with continuous infraclavicular brachial plexus block was higher when the same total dosage of 0.4% ropivacaine was compared with 0.2% ropivacaine (Ilfeld 2009 **Level II**, n=50, JS 3). There was no difference in analgesia but satisfaction scores were higher in patients who received the 0.2% infusion. Following hand surgery, continuous brachial plexus block (axillary approach) (0.1 or 0.2% ropivacaine) did not improve pain outcomes vs single-injection technique with a long-acting local anaesthetic (Salonen 2000 **Level II**, n=60, JS 4). This was also true in comparison with continuous infraclavicular blocks (Mariano 2011 **Level II**, n=20, JS 3).

5.8.4 | Lower limb blocks

Patient falls following major surgery is a key concern. After TKA, inpatient falls occurred in 1.6% and this event was associated with increasing age and higher comorbidity burden, whereas PNB did not increase the risk (OR 0.85; 95%CI 0.71 to 1.03) (Memtsoudis 2014 **Level IV**, n=191,570). Following TKA, continuous lumbar plexus block was associated with an increased risk of inpatient falls vs single-injection block or no block (OR 3.85; 95%CI 1.52 to 9.72) (NNH 59) (5 RCTs, n=1,595) (Johnson 2013 **Level III-3 SR**, 10 studies, n=4,014). The risk of falls with FNB was not different from ACB following total knee arthroplasty, but patients receiving ACB had significantly increased quadriceps motor strength (Elkassabany 2016 **Level II**, n=62, JS 5).

5.8.4.1 | Femoral nerve block

Femoral nerve block (FNB) either as a continuous (7 RCTs) or single-injection (6 RCTs [FNB alone] & 2 RCTs [FNB and sciatic PNB]) technique vs IV PCA analgesia alone is associated with improved analgesia on movement, reduced morphine consumption and decreased incidence of nausea following TKA (Paul 2010 **Level I**, 23 RCTs, n=1,016). Compared with periarticular infiltration of local anaesthetic (LIA), continuous FNB for TKA reduced opioid consumption and improved functional indicators at 6 wk (Carli 2010 **Level II**, n=40, JS 4). A similar study (infiltration vs continuous FNB) reported no significant difference in opioid consumption; however, 37% of patients who received the FNB experienced quadriceps weakness vs 0% in the infiltration group (Chaumeron 2013 **Level II**, n=60, JS 5). Continuous FNB combined with single-injection sciatic block resulted in better pain relief vs IT morphine (Alvarez 2017 **Level II**, n=40, JS 2). For more information on any differences between the local anaesthetics used for FNBs see Section 4.4.2.

5.8.4.2 | Fascia iliaca compartment and lateral femoral cutaneous nerve block

Single-injection fascia iliaca compartment block (FICB) provided similar postoperative analgesia to FNB following anterior cruciate ligament repair (Farid 2010 **Level II**, n=23, JS 3); and to '3-in-1' nerve block following knee joint arthroscopy and meniscal repair (Wallace 2012 **Level II**, n=60, JS 3). Suprainguinal FICB was opioid-sparing following THA vs no block (Desmet 2017 **Level II**, n=88, JS 5). However, effect on mobilisation was not recorded, which is relevant because FICB may have resulted in motor block delaying early mobilisation. Following a posterior approach to THA under spinal anaesthesia, US-guided lateral FNB with ropivacaine 0.75% 8 mL had no effect on analgesic outcomes at 4 h vs placebo (Thybo 2016 **Level II**, n=100, JS 5). All patients received paracetamol and ibuprofen.

Continuous FICB provided similar postoperative analgesia to continuous FNB over 48 h following TKA (Brisbane 2010 **Level II**, n=98, JS 2).

5.8.4.3 | Adductor canal and distal femoral triangle block

Recent anatomical studies point to the importance of the nerve to vastus medialis innervating the anteromedial knee capsule (Burckett-St Laurant 2016 **BS**). Research into the anatomy of the adductor canal and femoral triangle has supported the development of US-guided motor-sparing techniques. Since 2014, there has been a vast literature published on adductor canal block (ACB) compared to different combination therapies. However, interpreting the results of RCTs with ACB as an intervention is confounded by lack of consistency in how the block is implemented. It is likely in many RCTs that the ACBs were performed in the femoral triangle and not in the adductor canal. There has been extensive dialogue on this topic with one group describing how the apex of the femoral triangle (and hence the adductor canal which is located between the femoral triangle apex and the adductor hiatus) can be defined using US (Wong 2017 **BS**). The apex of the femoral triangle can be identified using US as where the medial borders of the adductor longus and sartorius intersect. This knowledge permits block placement at a consistent location where the nerve to vastus medialis and saphenous nerve are closely located. In contrast, but also to maintain consistency, other investigators perform ACB exactly halfway 'mid-thigh' between the anterior iliac spine and the cephalad border of the patella (Jaeger 2012 **Level II**, n=42, JS 5). Subsequent studies have defined the optimal anatomical location further. 'Mid-thigh' placement has been compared to the more distal true adductor canal catheter location, where the superficial femoral artery descends towards the adductor hiatus in 2 RCTs with contrasting results post TKA. One found the median pain score on POD 1 was reduced with the proximal vs the distal catheter placement (0.5/10 vs 3.0/10); however the worst pain scores were not different (Sztain 2018 **Level II**, n=50, JS 4).

While the second concluded continuous distal ACB provided noninferior analgesia to mid-thigh positioning (Meier 2018 **Level II**, n=73, JS 5). Combined distal femoral triangle/obturator blockade was superior to LIA in patients having TKA (Runge 2018 **Level II**, n=74, JS 5). The median 20-h morphine consumption was 6 mg (IQR 2 to 18) vs 20 mg (12 to 28) respectively with no difference in LOS.

Adductor canal block compared to placebo

ACB reduced opioid consumption and pain scores vs placebo after TKA (Hanson 2014 **Level II**, n=80, JS 5; Grevstad 2014 **Level II**, n=50, JS 5; Jenstrup 2012 **Level II**, n=75, JS 4; Jaeger 2012 **Level II**, n=42, JS 5). Single-injection ACB with bupivacaine 0.25% 10 mL vs 0.9% saline in addition to LIA with ropivacaine 0.2% 100 mL resulted in clinically relevant improvements in analgesia outcomes (opioid consumption, pain scores) at 36 h (Nader 2016 **Level II**, n=40, JS 5).

Adductor canal compared to femoral nerve blockade

In volunteer studies, ACB produced less loss of quadriceps strength vs FNB (8 vs 49%) (Jaeger 2013 **Level II EH**, n=12, JS 5); with minimal impact on balance (Kwofie 2013 **Level II EH**, n=16, JS 5).

Following TKA, ACB vs FNB results in similar control of postoperative pain (no differences in pain at rest and with mobilisation, rescue opioid requirements and patient satisfaction) with reduced likelihood of quadriceps weakness and improved mobilisation leading to better functional recovery (Kuang 2017 **Level I** [PRISMA], 9 RCTs, n=609; Hussain 2016 **Level I**, 6 RCTs, n=447) (6 RCTs overlap).

Studies published subsequent to the meta-analyses or not included confirm these findings. Pre-block maximum voluntary isometric contraction (MVIC) of the quadriceps increased at 60 min in patients who received ACB 24 h after TKA with ropivacaine 0.75% 30 mL vs placebo (median 170% vs 93%) (Sorensen 2016 **Level II**, n=64, JS 5). Despite overall better motor function associated with ACB, decrease in MVIC (defined as MVIC <75% of pre-block values) occurred in 5/64 patients and 4 of these were unable to perform the 'Timed Up and Go' test. This underscores the importance of a thorough functional assessment and falls prevention program. Continuous FNB vs continuous ACB showed no difference in analgesic outcomes and early recovery, although quadriceps motor strength with ACB was increased (Seo 2017 **Level III-1**, n=43). Time to discharge did not differ with continuous ACB vs continuous FNB following unicompartmental knee arthroplasty despite more patients satisfying discharge criteria on POD 2 in the ACB group (Sztain 2015 **Level II**, n=30, JS 3). More ACB recipients, despite significantly worse dynamic pain scores on day of surgery and POD 1, ambulated >30 m than FNB recipients.

Adductor canal block compared to LIA

There was no difference in the 'Timed Up and Go' test (46, 45 and 52 s) on POD 2 (primary outcome) with LIA/placebo blocks vs LIA/ACB vs LIA/ACB/IT morphine (Biswas 2018 **Level II**, n=201, JS 5). However, pain control was improved in patients randomised to LIA/ACB/IT morphine. Combined ACB/LIA reduced pain on walking on POD 1 vs ACB block alone or LIA alone (Sawhney 2016 **Level II,** n=151, JS 5). ACB vs LIA following TKA reduced opioid consumption at 24 h (6 vs 13 mg) and at 48 h (10 vs 25 mg) and pain scores at 6 to 16 h (by 1.2 to 1.5/10) (Kampitak 2018 **Level II**, n=60, JS 5). See also Section 5.8.2.1 below.

Adductor canal block compared to other peripheral nerve block combinations

Patients received continuous ACB and LIA for TKA and were randomised to receive in addition: obturator, tibial or both nerve blocks (Kampitak 2019 **Level II**, n=90, JS 4). Patients who received all three blocks had superior analgesia and mobilisation outcomes, and reduced opioid use (2 mg vs 4 mg and 6 mg morphine at 24 h). Continuous ACB vs sham catheter inserted on POD 1 decreased opioid consumption and pain scores at 0–20 h following insertion (ie on POD 2) and improved function at 3 wk (Leung 2018 **Level II**, n=165, JS 4). Epidural analgesia was used as the analgesic technique in the first 24 h and multimodal analgesia (eg NSAID or Cox II inhibitors) was

not used. Due to withdrawals only 70 patients completed the study which may have introduced bias.

Adductor canal block – single-injection dose and infusion considerations

There was no meaningful difference in quadriceps strength to 4 h with 10 mL vs 30 mL ropivacaine 0.1% for ACB (Jaeger 2015b **Level II EH**, n=26, JS 5). Both volumes produced meaningfully reduced tonic heat pain response indicating successful saphenous block. The ED_{95} (minimum effective anaesthetic volume in 95% of the subjects) to fill the distal adductor canal estimated on MRI was 20 mL (Jaeger 2015a **Level III-2 EH**, n=40). The ED_{50} (minimum effective anaesthetic volume in 50% of the subjects) needed for a 30% decrease in quadriceps strength was determined used the Dixon-Massey up-and-down method in patients having arthroscopic knee surgery as being 46.5 mL (95% confidence interval, 45.01-50.43 mL) (Johnston 2017 **Level III-2**, n=26). This volume is significantly higher than standard doses used in clinical practice.

Bilateral continuous ACB was established in volunteers with one limb of each subject randomly assigned to a continuous infusion of 8 mL/h or automated hourly boluses of 8 mL (Monahan 2016 **Level II EH**, n=24, JS 5). Tolerance to transcutaneous electrical stimulation in the territory of the anterior branch of the medial femoral cutaneous nerve was evaluated at 8 h with equivalent cutaneous analgesia (non-inferiority). There were no differences in secondary endpoints such as cutaneous analgesia at later time points or motor blockade. Continuous infusion 7 mL/h was compared to intermittent boluses (23 mL/3 h) with no difference in opioid consumption and other analgesic outcomes following TKA (Jaeger 2018 **Level II**, n=110, JS 5).

5.8.4.4 | Sciatic nerve block

After lower extremity surgery (Ilfeld 2002 **Level II**, n=30, JS 4) and foot surgery (White 2003 **Level II**, n=24, JS 5), continuous popliteal sciatic nerve analgesia resulted in better pain relief, lower opioid requirements and fewer adverse effects compared with opioids alone. The benefit of sciatic nerve block in addition to single-injection and continuous FNB for analgesia following TKA remains unclear (8 RCTs [various comparators]) (Paul 2010 **Level I**, 23 RCTs, n=1,016).

Interspace between the Popliteal Artery and the Capsule of the Posterior Knee (iPACK) block

iPACK block is a motor sparing block following TKA. It is likely iPACK results in blockade of a plexus formed by the posterior division of the obturator nerve and the tibial nerve that innervates the posterior knee capsule (Tran 2019 **BS**). ACB and iPACK block when added to periarticular injection had lower pain scores on ambulation on POD 1 (Kim 2019a **Level II**, n=86, JS 5). ACB/iPACK block vs ACB resulted in improved pain scores from 8 h to POD 2 (Sankineani 2018 **Level III-2**, n=120).

5.8.4.5 | Lumbar plexus

Following THA, there was no difference for continuous posterior lumbar plexus block vs continuous FNB in postoperative pain scores, however FNB recipients had more motor block impairing ambulatory function (Ilfeld 2011b **Level II**, n=50, JS 3). Lumbar plexus block resulted in a modest improvement in pain in the early postoperative period following hip arthroscopy (YaDeau 2012 **Level II**, n=84, JS 5). Lumbar plexus block vs ACB provided similar analgesia following unicondylar knee arthroplasty at 6 h (Henshaw 2016 **Level II**, n=150, JS 5). There were also no other differences in analgesia outcomes at other time points to 24 h. Quadriceps motor strength was better in the ACB group.

5.8.5 | Truncal blocks

Truncal blocks are increasingly used to provide analgesia after surgery; the number of techniques for these blocks is continuously increasing and most are performed with US-guidance; a detailed systematic review on the current developments of these techniques with regard to anatomy (10 studies [cadaver], 6 [volunteer/imaging], 2-4 technical descriptions), clinical outcomes and complications has been published (3 SRs, 4 RCTs, 12 studies, 4 CR) (Abrahams 2016 **Level IV SR**, 42 manuscripts, n unspecified).

5.8.5.1 | Paravertebral blocks

Paravertebral block (PVB) is a technique that is likely to benefit from US-guidance because the landmark technique has been associated with a high proportion of misplaced catheters (Luyet 2012 **Level IV**, n=31), and US-guidance can improve the needle trajectory (Abdallah 2014a **NR**). All forms of PVB combined (single-injection, multi-level injection and continuous infusion) demonstrate superior analgesia for up to 48 h following breast surgery vs systemic analgesia, with a lower incidence of PONV (RR 0.26; 95%CI 0.13 to 0.5) and few specific adverse effects (Schnabel 2010 **Level I** [PRISMA], 15 RCTs, n=877). PVBs with general anaesthesia or propofol sedation reduce pain scores at rest and movement (22 RCTs, n=1,714) and reduce opioid consumption (16 RCTs, n=1,406) up to 72 h after breast surgery (Terkawi 2015 **Level I** [PRISMA], 24 RCTs, n=1,822) (14 RCTs overlap). Addition of fentanyl (11 RCTs) and multilevel injection (5 RCTs) improve quality of analgesia. Reduced nausea (OR 0.44; 95%CI 0.31 to 0.61) (12 RCTs) and vomiting (OR 0.42; 95%CI 0.25 to 0.71) (9 RCTs) and small decrease in hospital LOS (SMD -0.60; -1.13 to -0.06) (6 RCTs) are also observed. A further study confirmed an improved quality of recovery (Abdallah 2014b **Level II**, n=64, JS 5).

For breast cancer surgery, PVB (6 RCTs, n=419) reduces CPSP (OR 0.61; 95%CI 0.39 to 0.97) (NNT 11) (Weinstein 2018 **Level I** (Cochrane), 63 RCTs, n=3,027). See also Section 1.4.6.1.

For thoracotomy, paravertebral or epidural techniques provide superior analgesia vs IT, interpleural, IC and systemic opioid techniques; PVBs cause less hypotension than epidural analgesia and reduce the incidence of pulmonary complications vs systemic analgesia (Joshi 2008 **Level I**, 74 RCTs, n unspecified). Following thoracotomy, there is moderate-quality evidence that shows comparable analgesic efficacy at rest and after coughing with PVB vs epidural analgesia (3 to 6 RCTs [2-6, 24 & 48 h]) (Yeung 2016 **Level I** [Cochrane], 14 RCTs, n=698). There is low to very low-quality evidence that showed no significant difference in mortality and major complications. There is moderate-quality evidence that PVB has a superior minor complication risk vs thoracic epidural analgesia including hypotension (RR 0.16; 95%CI 0.07 to 0.38) (8 RCTs, n=445), nausea and vomiting (RR 0.48; 95%CI 0.30 to 0.75) (6 RCTs, n=345), pruritus (RR 0.29; 95%CI 0.14 to 0.59) (5 RCTs, n=249) and urinary retention (RR 0.22; 95%CI 0.11 to 0.46) (5 RCTs, n=258). These results are consistent with a parallel meta-analysis showing that continuous PVB reduces the incidence of nausea, vomiting, hypotension and urinary retention vs thoracic epidural analgesia, wound infiltration or IV opioids while providing comparable post-cardiothoracic surgery analgesia (Scarfe 2016 **Level I** [PRISMA], 23 RCTs, n= 1,120) (12 RCTs overlap).

Paravertebral block for sternotomy and open liver resection

Most of the evidence for PVB is following breast surgery or thoracotomy, but there are a limited number of studies following sternotomy for cardiac surgery (eg 2 of 18 RCTs comparing PVB and TEA in Scarfe 2016 **Level I**, 23 RCTs, n=1,120). A comparison of continuous bilateral thoracic PVB with bilateral continuous SC lidocaine infusions in patients undergoing cardiac surgery found no difference in postoperative morphine requirements (Lockwood 2017 **Level II**, n=50, JS 5). Appropriately, the authors highlight the risk of local anaesthetic systemic toxicity (LAST) with

continuous bilateral PVBs in patients with ischaemic heart disease and extensive medical comorbidities. The risk of LAST is confirmed in patients having coronary artery bypass surgery (CABG) with continuous bilateral thoracic PVB, where plasma ropivacaine concentrations consistent with toxicity and one case of toxicity occurred with dosages in the range recommended by manufacturers (Ho 2016 **Level IV PK**, n=8).

Following elective open liver resection, patients were randomised to receive either TEA or bilateral T7 or T8 PVB with ropivacaine 0.2% infused for 3 d (Schreiber 2016 **Level II**, n=87, JS 3). There was a statistically significant, but clinically modest reduction in pain score in the epidural group.

Paravertebral block for breast cancer surgery

For mastectomy, PVB reduces the risk of CPSP at 12 mth postoperatively (OR 0.43; 95% CI 0.28 to 0.68) (18 RCTs, n=1,297) (Weinstein 2018 **Level I** (Cochrane), 63 RCTs, n=3,027).

5.8.5.2 | Intercostal and interpleural block

Following a single intercostal block (ICB) using 0.5% bupivacaine, segmental analgesia can last up to 20 h (Perttunen 1995 **Level II**, n=45, JS 2). Multilevel ICBs improve analgesia vs systemic opioids alone, particularly during POD 1 (Detterbeck 2005 **Level I**, 12 RCTs [ICB vs systemic opioids], n=477); pulmonary function tests are better preserved, although pulmonary complications are not consistently reduced. There are no consistent differences in analgesia outcomes for multilevel ICBs in comparison with epidural analgesia (Detterbeck 2005 **Level I**, 5 RCTs [ICB vs epidural], n=140), although duration of follow-up was not specified and individual studies were small. Following thoracotomy, surgically delivered ICBs with liposomal bupivacaine provided improved analgesia on POD 1 and 3 vs TEA (technique unspecified) with hydromorphone PCA used as rescue in both groups (Khalil 2015, **Level III-2,** n=85).

Analgesia can be achieved using a subpleural catheter placed in the space posterior to the parietal pleura alongside the paravertebral area, or more laterally in the IC region. Following posterolateral thoracotomy, patients receiving TEA had superior pain control vs continuous subpleural analgesia (Kanazi 2012 **Level II**, n=42, JS 4; Debreceni 2003 **Level II**, n=50, JS 5). However, similar analgesia was achieved for up to 5 d with epidural vs IC catheter local anaesthetic infusions (Luketich 2005 **Level II**, n=91, JS 3).

Multilevel US-guided IC nerve blocks provided superior pain relief for 24 h vs systemic analgesics alone after percutaneous nephrolithotomy (Ozkan 2013 **Level II**, n=40, JS 5).

The incidence of pneumothorax following multilevel ICBs has been estimated at 0.07% based on data from approximately 100,000 injections (Moore 1975 **Level IV**, n=10,941 [patients]).

Interpleural local anaesthetic infusion has not been found to be superior to systemic opioid analgesia in thoracotomy patients (Detterbeck 2005 **Level I**, 11 RCTs [interpleural], n=287). Interpleural analgesia (intermittent bolus injection technique) was compared to continuous TEA following minimally invasive thoracoscopic surgery (Ishikawa 2012 **Level II**, n=40, JS 1); pain scores were not different between the groups. Interpleural analgesia is superior to systemic analgesia following open cholecystectomy but not following laparoscopic cholecystectomy or nephrectomy (Dravid 2007 **NR**).

5.8.5.3 | Erector spinae plane block and retrolaminar block

The erector spinae plane block (ESPB), an US-guided technique with plane of injection between the thoracic vertebral transverse process (often mid-thoracic) and the erector spinae muscle was described in 2016 for a chronic pain indication (Forero 2016 **CR**). The premise of erector spinae plane block and retrolaminar blocks are that spinal ventral and posterior rami are accessed with

local anaesthetic injected posterior to, instead of injection anterior to the costotransverse ligament. For retrolaminar blocks, the local anaesthetic is injected between erector spinae muscle and the thoracic lamina. It is debated whether the ESPB is a paravertebral variant involving nerve roots (Tsui 2019a **Level IV**, n=242) vs a myofascial plane block. Paravertebral spread of 15 mL radiocontrast was demonstrated during fluoroscopic study through continuous ESPB (Ueshima 2018 **Level IV**, n=3). In unembalmed cadavers, US-guided 20 mL injectate into ESP at T5 involved dorsal rami in 80%, ventral rami in 20%, but dorsal ganglion in only 10% (Ivanusic 2018 **Level IV BS**, n=10 [cadavers]). A second cadaver study assessed an injection on opposite sides into ESP and retrolaminar space with 20 mL injectate at T5; spread to the epidural and neural foraminal spaces over 2 to 5 levels was demonstrated with MRI and anatomical dissection (Adhikary 2019 **Level IV BS**, n=3 [cadavers]).

For ESPB studies, single-injection techniques are used in 80.2%, intermittent boluses in 12% and continuous infusions in 7.9% (Tsui 2019a **Level IV SR**, 85 studies, n=242). Multimodal analgesia is used in 91% of cases. Sensory changes are reported in 35% of cases; 35% report reduced opioid use. ESPB versus systemic analgesia after breast (1 RCT: Gurkan 2018 **Level II**, n=50, JS 2), cardiac surgery (1 RCT: Krishna 2019 **Level II**, n=106, JS 4) and laparoscopic cholecystectomy (1 RCT: Tulgar 2018 **Level II**, n=30, JS 1) improves analgesia and/or reduces rescue requirements (De Cassai 2019 **Level I** [PRISMA], 4 RCTs, n=242) (2 of 4 RCT overlap with Tsui 2019a). Following sternotomy (for midline cardiac surgery), continuous bilateral ESPB vs TEA resulted in similar pain scores for the first 12 h and improved pain scores between 24 h and 48 h (1 RCT: Nagaraja 2018 **Level II**, n=50, JS 3).

Subsequent RCTs not included in these SRs are in line with these results. For modified radical mastectomy, similar results were demonstrated for ESPB vs routine pain management (Singh 2019 **Level II**, n=40, JS 4). Following open epigastric hernia repair, ESPB vs sham block reduced pain scores and decreased perioperative analgesic requirements (Abu Elyazed 2019 **Level II**, n=60, JS 3). Following abdominal hysterectomy, bilateral ESPB vs sham block did not result in a clinically significant reduction in postoperative fentanyl consumption, but achieved clinically significant pain reduction for 12 h (Hamed 2019 **Level II**, n=60, JS 4).

ESPB vs TAP block following laparoscopic cholecystectomy leads to reduction of opioid requirements and pain intensity (Ciftci 2020 **Level II**, n=60, JS 3; Altiparmak 2019a **Level II**, n=68, JS 4).

For video-assisted thoracoscopic surgery (VATS), EPSB vs serratus plane block reduced pain intensity from 4 to 6 h and increased time to rescue analgesia (Gaballah 2019 **Level II**, n=60, JS 4).

5.8.5.4 | Pectoralis nerves and serratus plane blocks

US-guided pectoralis nerves (PECS) blocks and serratus anterior plane (SAP) blocks are regional analgesia techniques of the thorax (Battista 2020 **NR**). PECS and SAP blocks were developed as a less invasive alternative to PVB for breast surgery. In PECS I blocks the injectate is injected between pectoralis major and minor only. PECS II blocks refer to an US-guided block of the medial and lateral pectoral nerves (target plane between pectoralis major and minor muscles) combined with lateral cutaneous branch of the intercostal nerves (target plane between the pectoralis minor and serratus anterior muscles).

PECS I blocks vs placebo in the setting of multimodal analgesia did not reduce pain scores in PACU following tissue preserving breast cancer surgery (Cros 2018 **Level II**, n=128, JS 5).

Combined PECS I and PECS II blocks vs control reduced postoperative pain scores for 24 h and decreased morphine consumption for 12 h following modified radical mastectomy surgery (Bashandy 2015 **Level II**, n=120, JS 3). After mastectomy, PECS II block vs placebo resulted in less pain and reduced opioid requirements during PACU stay (Versyck 2017 **Level II**, n=140, JS 5). Similarly, for breast cancer surgery, PECS II blocks vs control had an opioid-sparing effect and resulted in better mobilisation of the shoulder and patient satisfaction (Neethu 2018, **Level II**, n=60,

JS 2). Following radical mastectomy, PECS II block provided superior analgesia to ESPB (tramadol requirements as primary outcome) (Altiparmak 2019b **Level II**, n=38, JS 3).

Postoperative insertion of combined bilateral PECS II blocks and drain site infiltration (35 mL bupivacaine 0.25%) vs no block (all participants received paracetamol/tramadol) following sternotomy for cardiac surgery reduced pain scores and requirement for intensive care resources (Kumar 2018, **Level II**, n=40, JS 3). After paediatric cardiac surgery via thoracotomy, PECS II and SAP blocks vs IC blocks resulted in statistically significant, but clinically modest, improvement in analgesia (Kaushal 2019 **Level II**, n=108, JS 3).

SAP block was superior (opioid consumption and first request for analgesia) to no block for mastectomy (Rahimzadeh 2018 **Level II**, n=60, JS 2). SAP block vs PVB for modified radical mastectomy was inferior with regard to time to commence PCA use (245 min vs 346 min) and opioid requirements, but with similar pain scores (Gupta 2017 **Level II**, n=50, JS 5). Similarly, following modified radical mastectomy, PVB vs SAP block prolonged analgesia (11 vs 6 h) (Hetta 2016 **Level II**, n=64, JS 3).

Following VATS, SAP block vs placebo improved 40-item Quality of Recovery (QoR-40) score at 24 h after surgery (Kim 2018a **Level II**, n=90, JS 5). SAP block vs systemic multimodal analgesia reduced pain scores following thoracoscopic surgery for 8 h (Semyonov 2019 **Level II**, n=104, JS 1). SAP block vs TEA had reduced effects on blood pressure (primary outcome) following thoracotomy (Khalil 2017 **Level II**, n=60, JS 3).

5.8.5.5 | Sternal bed blocks

PECS blocks will not block the anterior cutaneous branch of the intercostal nerves. However, transversus thoracis block, a sternal bed block with local anaesthetic injected into the neurovascular plane superficial to the transversus thoracis muscle, will result in anterior cutaneous branch block. Injections of ropivacaine 0.5% (total dose <5 mg/kg) into the 2nd to 6th parasternal intercostal spaces were superior vs placebo (same volume of sodium chloride 0.9 %) for treatment of postoperative pain in pediatric patients undergoing midline cardiac surgery (Chaudhary 2012 **Level II**, n=30, JS 4). PECS block combined with transversus thoracis block vs PECS block alone reduced pain intensity following mastectomy (Ueshima 2017a **Level II**, n=70, JS 3).

Surgeon administered sternal bed blocks combined with systemic analgesia vs systemic analgesia alone resulted in clinically relevant reduced pain scores for 24 h following CABG (Dogan Baki 2016 **Level II**, n=81, JS 4). This study included a 6 mth follow-up, where there was no difference in the incidence of chronic pain

5.8.5.6 | Transversus abdominus plane block

Transversus abdominis plane block (TAPB) is used to provide analgesia following abdominal surgery. TAPB by US-guidance has generally replaced use of landmark technique. Independent of the type of surgery (abdominal laparotomy, abdominal laparoscopy, and Caesarean section) US-guided TAPB vs sham or no block reduce IV morphine consumption at 6 h (MD -6 mg; 95%CI −7 to −4) and 24 h (MD −11 mg; 95%CI −14 to −8) vs control or placebo (Baeriswyl 2015 **Level I** [PRISMA], 31 RCTs, n=1,611). In addition, pain scores are reduced at rest (MD −10/100; 95%CI −15 to −5) and on movement (MD −9/100; 95%CI −14 to −5) at 6 h, but not PONV or pruritus. These effects are not seen in patients receiving long-acting spinal opioid, and were independent of timing of injection, approach used or the use of systemic multimodal analgesia. A parallel systematic review in all types of surgery describes similar effects; TAPB vs placebo reduces pain intensity at 6 h (SMD -1.4/10; 95%CI -1.9 to -0.8) (23 RCTs, n=1,092), at 12 h (SMD -2.0/10; 95%CI -2.7 to -1.4) (18 RCTs, n=930), at 24 h (SMD -1.2/10; 95%CI -1.6 to -0.8) (33 RCTs) and opioid requirements at 24 h (MED -14.7 mg; 95%CI -18.4 to -11.0) (28 RCTs) (Brogi 2016 **Level I** [PRISMA],

51 RCTs, n unspecified) (significant RCT overlap). These results remain consistent across surgical types, but analgesic efficacy of TAPB is inferior to IT morphine. These results are also in line with two preceding meta-analyses specifically looking at effects of TAPB in Caesarean section (Mishriky 2012 **Level I**, 9 RCTs, n=524) (4 RCTs overlap with Baeriswyl 2015) and in laparoscopic surgery (De Oliveira 2014 **Level I**, 10 RCTs, n=633) (all 10 RCTs overlap with Baeriswyl 2015). RCTs not included in these meta-analyses have shown contradictory results (Soltani Mohammadi 2014 **Level II**, n=67, JS 5; Rao Kadam 2013 **Level II**, n=42, JS 3).

For a wide range of open and laparoscopic abdominal surgery in adults and children, epidural analgesia vs TAPB provides similar analgesia (MD 0.5/10; 95%CI -0.1 to 1.0) (6 RCTs [adult], n=310), but TAPB reduces the risk of hypotension (RR 0.13; 95%CI 0.04 to 0.38) (4 RCTs, n=191) and LOS (MD: -0.6 d; 95%CI: -0.9 to -0.3) (3 RCTs, n=146) (Baeriswyl 2018 **Level I** [PRISMA], 10 RCTs, n=505).

After abdominal hysterectomy, TAPB vs sham block or no block reduce 24 h opioid consumption (3 RCTs, n=126), pain scores at 2 h (6 RCTs, n=274) and 24 h (5 RCTs, n=228), PONV (6 RCTs, n=345) and prolong time to analgesic request (4 RCTs, n=238) (Zhou 2018 **Level I** [PRISMA], 13 RCTs, n=841) (3 RCTs overlap with Baeriswyl 2015). After abdominal hysterectomy, TAPB provided the best pain relief and the lowest opioid rescue requirements vs epidural analgesia and vs parenteral analgesia (Mathew 2019 **Level II**, n=60, JS 4).

In adults undergoing lower abdominal surgery, TAPB vs local anaesthetic infiltration provided superior analgesia at 24 h, although pain scores at 2 and 4 h postoperatively were similar (Yu 2014 **Level I**, 4 RCTs, n=196) (3 RCTs overlap with Baeriswyl 2015). TAPB vs local anaesthetic infiltration reduces 24 h morphine consumption (MD -3.85 mg; 95%CI -7.47 to -0.22) (Guo 2015 **Level I**, 5 RCTs, n=127) (3 RCTs overlap with Baeriswyl 2015).

Both landmark and US-guided TAPB have been complicated by liver trauma (Lancaster 2010 **CR**; Farooq 2008 **CR**). For paediatric use, see Section 10.6.2.3.

5.8.5.7 | Quadratus lumborum block

Quadratus lumborum block (QLB) has been proposed as a superior alternative to US-guided TAPB (Elsharkawy 2019 **NR**; Ueshima 2017b **NR**). With QLB, local anaesthetic is injected anterior, posterior or lateral to the posterior abdominal wall muscle quadratus lumborum. Posterior QLB vs placebo or control reduced morphine requirements and pain intensity after Caesarean section (Krohg 2018 **Level II,** n=40, JS 5; Mieszkowski 2018 **Level II,** n=58, JS 3; Blanco 2015 **Level II,** n=50, JS 5). Posterior QLB vs TAP block reduced morphine requirements while providing comparable analgesia after Caesarean section (Blanco 2016 **Level II,** n=75, JS 4).

Following laparoscopic gynaecological surgery posterior QLB vs control improved pain relief at rest and on movement (Ishio 2017 **Level II,** n=70, JS 2). QLB was not superior to systemic IV lidocaine for the reduction of morphine requirements 24 h after laparoscopic colorectal surgery (Dewinter 2018 **Level II**, n=125, JS 5).

For paediatric use see Section 10.6.2.3.

5.8.5.8| Other abdominal wall blocks

Ilioinguinal and iliohypogastric nerves innervate the lower abdominal wall and groin region (Chin 2017 **NR**). These nerves can be blocked using landmark or ultrasound-guided techniques in the immediate vicinity of the anterior superior iliac spine. Anatomical variability likely contributes to the variable success rate of the Ilioinguinal-iliohypogastric nerve blocks. This variability together with the heterogeneity of published trials, means that there are no specific evidenced-based recommendations for this procedure. The clinical efficacy of rectus sheath blocks in the general surgical (open and laparoscopic) and obstetric populations is unclear. Transversalis fascia plane has been described in case reports.

5.8.6 | Head and Neck Blocks

5.8.6.1 | Sphenopalatine ganglion block

After endoscopic sinus surgery, sphenopalatine ganglion block vs placebo or control improved pain intensity and PONV (Kim 2019b **Level I** [PRISMA], 8 RCTs, n=441). Topical sphenopalatine ganglion block was associated with improved results for treatment of postdural puncture headache (PDPH) vs epidural blood patch (Cohen 2018 **Level IV**, n=81).

5.8.7 | Periarticular and intra-articular analgesia

The use of intra-articular (IA) infusions of bupivacaine with adrenaline has been cautioned against because of reports of glenohumoral chondrolysis following shoulder arthroscopy (Hansen 2007 **Level III-3**, n=189 [shoulders operated on]; Bailie 2009 **Level IV**, n=23). Chondrotoxic effects have been shown for all local anaesthetics in in-vitro studies of human knee cartilage (Jayaram 2019 **Level III-2 BS** [PRISMA], 16 studies, n unspecified). Chondrotoxicity is worsened by coadministration of corticosteroids; ropivacaine at concentrations ≤0.5 % was the least chondrotoxic LA. See also Section 4.4.3.1.

IA NSAIDs have demonstrated analgesic efficacy over systemic administration in some studies but the overall benefit is less clear (see Section 4.2.3.1). An analgesic effect for IA morphine following arthroscopy vs placebo cannot be shown (Rosseland 2005 **Level I**, 46 RCTs, n=3,166).

5.8.7.1 | Local infiltration analgesia

LIA refers to the systematic intraoperative injection of local anaesthetics in the periarticular and IA regions; LIA may also be referred to as periarticular infiltration. There have been methodology issues in LIA studies: lack of blinding, lack of placebo, lack of supplemental agents in controls (eg ketorolac), variable use of 'top-up' catheters, inferior results with established techniques (peripheral nerve or epidural block) compared to the literature, the use of traditional recovery programs with low activity (limiting the assessment of therapies on early functional recovery) and inadequate pain assessment (Andersen 2014 **Level I**, 27 RCTs, n=1,644). Other limitations of LIA studies have included non-uniform use of both non-opioid and opioid analgesia across treatment groups, poorly defined multimodal analgesia therapies and mobilisation pathways (Kehlet 2011 **NR**). The role of NSAIDs introduced via LIA vs systemic administration is also unclear (see Section 4.2.3.3). Similarly, there seems to be little benefit of adding opioids such as morphine; morphine 0.1 mg/kg as a component of LIA with ropivacaine/ketoprofen/methylprednisolone/adrenaline in one side vs no morphine in patients having bilateral TKA had no effect on pain, swelling or ROM (Iwakiri 2017 **Level II**, n=53, JS 4).

Total knee arthroplasty: LIA compared to placebo or no injection

Compared to placebo or no injection in TKA, LIA (with local anaesthetics in various combinations with NSAID, steroids, opioids and adrenaline) was associated with reduced pain scores and reduced opioid consumption for up to 32 h (Andersen 2014 **Level I**, 7 RCTs [LIA in TKA vs placebo/no injection], n=328); there was a high risk of bias with unbalanced systemic analgesic regimens between groups. In patients having bilateral TKA, LIA improved pain outcomes vs periarticular placebo on the opposite side (Fajardo 2011 **Level II**, n=30, JS 2; Mullaji 2010 **Level II**, n=40, JS 5; Andersen 2008 **Level II**, n=12, JS 4). Reviews comparing LIA with placebo or no injection report that following

TKA LIA achieves superior analgesia and reduced opioid consumption, however the source RCTs were at high risk of bias because of lack of blinding (Xu 2014 **Level I**, 18 RCTs, n=1,858).

Total knee arthroplasty: LIA compared to epidural analgesia

In comparison to LIA in TKA, LEA has similar analgesic effects at rest for <24 h, but LIA achieves better analgesia at 48 h (MD −1.08/10; 95%CI −1.86 to −0.29) and 72 h (MD −0.82/10; 95%CI −1.24 to −0.4) (Yan 2016 **Level I**, 9 RCTs [TKA], n=537). Similarly, pain on movement was similar at <24 h, but better controlled by LIA at 48 h and LIA enabled a better range of movement at all time points.

Total knee arthroplasty: LIA compared to peripheral nerve blockade

When comparing FNB to LIA in TKA, most RCTs report either equal analgesic efficacy or a short-term benefit of LIA (Andersen 2014 **Level I**, 5 RCTs [LIA vs FNB in TKA], n=307; Fan 2016 **Level II**, n=157, JS 2; Ashraf 2013 **Level II**, n=50, JS 3; Ng 2012 **Level II**, n=16, JS 4). Interpretation of results is hindered by the multitude of techniques, leaving the analgesic benefit of LIA *per se* unclear.

LIA achieved similar time to readiness for discharge from hospital (mean 3.2 d) vs combined PCEA/FNB (Yadeau 2013 **Level II**, n=90, JS 3). A single-injection FNB when combined with epidural analgesia resulted in reduced pain vs LIA during the first 24 h (Reinhardt 2014 **Level II**, n=94, JS 5). LIA has superior analgesic outcomes vs epidural analgesia (Andersen 2014 **Level I**, 3 RCTs [LIA vs epidural in TKA], n=204); these trials had high risk of bias because of incomplete blinding and high heterogeneity due to different systemic analgesic regimens between groups. In patients receiving epidural analgesia, there was no added analgesic or functional benefit from LIA vs placebo in the contralateral side for up to 14 d (Joo 2011 **Level II**, n=572, JS 5). When LIA was added to combined FNB and sciatic block (with spinal anaesthesia for the surgery), improved pain relief was only found at one time point postoperatively (0.6/10 ± 1.5 vs 1.7/10 ± 2.3) (Hinarejos 2016 **Level II**, n=50, JS 5). As there were no other differences in analgesic outcomes, the authors concluded that adding LIA to their regimen was not necessary.

Total hip arthroplasty

In THA, no additional analgesic benefit of LIA vs placebo LIA (5 RCTs) or no injection (2 RCTs) (added to systemic multimodal analgesia) is identified (Andersen 2014 **Level I**, 10 RCTs [THA], n=756). Compared with IT morphine (1 RCT) and epidural analgesia (1 RCT), LIA was reported to have similar or improved analgesic effects.

5.8.8 | Wound catheter infusion, instillation and wound infiltration

5.8.8.1 | Wound catheter local anaesthetic infusions and intermittent injection

Wound catheter local anaesthetic continuous infusion (21 RCTs) or intermittent injections (9 RCTs) provide minor analgesic benefits up to 48 h in obstetric and gynaecological surgery (6 RCTs), but do not improve analgesic outcomes following abdominal (7 RCTs) or other non-orthopaedic (urological, reconstructive or thoracic) surgery (Gupta 2011 **Level I**, 32 RCTs, n=1,999). LOS is not reduced (pooled for all surgery) (17 RCTs). Continuous wound infiltration with ropivacaine vs placebo leads to a reduction in pain scores and opioid consumption (Raines 2014 **Level I**, 14 RCTs, n=756) (4 RCTs overlap with Gupta 2011). Following Caesarean section, local anaesthetic wound infiltration (by infusion) reduces opioid consumption (MD −10.29 MME; 95%CI −18.36 to −2.21) (8 RCTs, n=441), but has limited effects on pain scores with movement at 24 h (MD −0.83/10; 95%CI −1.90 to −0.23) (7 RCTs, n=434) (Adesope 2016 **Level I**, 21 RCTs, n=1,435) (5 RCTs overlap with Gupta 2011). Local anaesthetic infusions (6 RCTs [continuous]), 2 RCTS [intermittent], 1 RCT [PCA]) via abdominal wound catheter vs epidural analgesia have equal analgesic efficacy for up to 48 h (7

RCTs, n=425) with a lower incidence of urinary retention (3 RCTs, n=160) (Ventham 2013 **Level I** [PRISMA], 9 RCTs, n=505); there was however considerable heterogeneity with variability in analgesic regimens, especially in the epidural arms. Epidural analgesia provided better pain relief than continuous wound infiltration at rest at 72 h (4 RCTs, n=289) (Li 2018a **Level** I, 16 RCTs, n=1,345) (8 RCTs overlap with Ventham 2013). There were no differences in pain score at rest or on mobilisation at 2 h, 12 h, 24 h and 48 h. Hypotension is more common in epidural vs wound infusion recipients (14 RCTs, n=1,350).

Continuous preperitoneal local anaesthetic infiltration is superior vs continuous subcutaneous infiltration (1 RCT, n=60) and vs placebo (9 RCTs, n=537), with similar analgesia vs active control (epidural analgesia or PCA) (13 RCTs, n =887) (Mungroop 2019 **Level I** [PRISMA], 29 RCTs, n=2,059). Preperitoneal wound catheter infusion of ropivacaine following colorectal surgery resulted in improved pain relief, opioid-sparing and earlier recovery of bowel function (Beaussier 2007 **Level II**, n=49, JS 5).

5.8.8.2 | Intraperitoneal instillation

Early postoperative abdominal pain is improved after laparoscopic cholecystectomy by the use of intraperitoneal local anaesthetic; the effect is better when given at the start of surgery vs instillation at the end of surgery (Boddy 2006 **Level I**, 24 RCTs, n=1,256). In laparoscopic gastric surgery, intraperitoneal local anaesthetic reduces postoperative abdominal pain intensity, the incidence of shoulder pain and opioid consumption (Kahokehr 2011 **Level I** [PRISMA], 5 RCTs, n=273).

5.8.8.3 |Local anaesthetic infiltration

Local anaesthetic infiltration vs a variety of controls for mastectomy did not improve analgesic outcomes (Tam 2015 **Level I** [PRISMA] 13 RCTs, n=1,150).

Infiltration of local anaesthetic into the scalp is used to treat postoperative pain following craniotomy. Preoperative scalp infiltration provides improved pain scores for up to 8 h postoperatively, with postprocedural infiltration improving analgesia for up to 12 h (Guilfoyle 2013 **Level I** [PRISMA], 7 RCTs, n=325).

5.8.9 | Topical application of local anaesthetics

Topical EMLA® cream (eutectic mixture of lignocaine and prilocaine) is effective in reducing the pain associated with venous ulcer debridement (Briggs 2012 **Level I** [Cochrane], 6 RCTs, n=343). When compared with EMLA® cream, topical amethocaine provides superior analgesia for superficial procedures in children, especially IV cannulation (Lander 2006 **Level I**, 6 RCTs, n=534). Topical tetracaine, liposome-encapsulated tetracaine and liposome-encapsulated lignocaine are as effective as EMLA® cream for dermal instrumentation analgesia in the ED (Eidelman 2005 **Level I**, 25 RCTs, n=2,096). See Sections 10.6.3.5 and 10.6.6 for use in penile surgery, 10.7.1 to 10.7.3 and 10.8.2 for procedures involving skin puncture use in children and Section 8.11.2 for use in the ED.

Topical local anaesthetic provides no analgesic benefit when performing flexible diagnostic nasoendoscopy, either alone or in combination with a vasoconstrictor (Conlin 2008 **Level I**, 8 RCTs, n=818; Nankivell 2008 **Level I**, 18 RCTs, n=1,356). Intraurethral instillation of lidocaine gel provides superior analgesia to lubricating gel during flexible cystoscopy (Aaronson 2009 **Level I**, 4 RCTs, n=411). Following tonsillectomy, local anaesthetics provide a modest reduction in post-tonsillectomy pain; administering the local anaesthetic on swabs appeared to provide a similar level of analgesia to that of infiltration (Grainger 2008 **Level I**, 13 RCTs [6 adult & 7 paediatric], n unspecified). Topical local anaesthetic gel and/or nebulised local anaesthesia of the nose and

pharynx reduced pain associated with nasogastric tube insertion in adults (OR 0.42; 95%CI 0.20 to 0.88) (Kuo 2010 **Level I**, 5 RCTs, n=212). See also paediatric Section 10.7.2.6.

The lignocaine 5% patch may reduce acute pain intensity following herpes zoster once lesions have healed (McCarberg 2013 **NR**).

5.8.10 | Neuromodulation

There is some emerging evidence that percutaneous peripheral nerve stimulation may be a promising alternative to infusions of local anaesthetics through a perineural catheter (Gabriel 2019 **NR**). In this technique, small gauge insulated electrical leads are placed percutaneously through needle that is placed remotely 0.5 to 3.0 cm from a peripheral nerve using US-guidance. The lead is connected to an external stimulator and narrow pulse duration electrical stimulation is applied to selectively activate pain-relieving fibres in a peripheral nerve trunk. This technique does not activate fibres that would result in muscle contractions, loss of strength or loss of proprioception. US-guided percutaneous peripheral nerve stimulation has been used successfully for analgesia following pain refractory to standard therapy following knee arthroplasty (Ilfeld 2017b **Level IV**, n=5). Following ambulatory rotator cuff repair, although initial pain control was inadequate, the later postoperative quality of analgesia (POD 1 to 14) was considered excellent (Ilfeld 2019a **Level II**, n=11, JS 5). Proof of concept studies have used percutaneous femoral nerve stimulation for ambulatory anterior cruciate ligament reconstruction (Ilfeld 2019b **Level II**, n=10, JS 5) and percutaneous sciatic nerve stimulation for ambulatory foot surgery (Ilfeld 2018 **Level II**, n=10, JS 5). Development issues with this technique include optimal lead location and insertion technique, the stimulating protocol and prevention of lead fracture/dislodgement.

5.8.11 | Safety

Regional anaesthesia techniques when performed with vigilance and professionalism are associated with a high degree of safety (Barrington 2013 **Level IV**, n=25,336 [PNBs in 20,021 patients]; Orebaugh 2012 **Level IV**, n=14,498 [PNBs]; Barrington 2009 **Level IV**, n=8,189 [PNBs in 6,950 patients]). Simple strategies such as preprocedural checklists, including a pre-block "*time-out*" ('Stop Before You Block') and a "*pause*", may help reduce the incidence of events such as wrong-site blockade (Barrington 2015 **GL;** ANZCA 2015 **GL**).

For paediatric data see Sections 10.6.1.3, 10.6.3.5 and Table 10.10.

5.8.11.1 | Anticoagulation

Caution should be used when considering and performing some peripheral nerve or plexus blocks in patients with impaired coagulation (see Section 5.9.2). This particularly applies to where the PNB is performed at a deep location that prevents external compression, should bleeding occur.

5.8.11.2 | Nerve injury and postoperative neurologic symptoms

A new onset postoperative nerve injury regardless of severity is of concern to patients and healthcare providers. Methods used to capture, define and report neurologic outcomes vary considerably. A multicentre registry using systematic postoperative contact with all patients reported the incidence of block-related nerve injury as 4/10,000 blocks (95%CI 0.8 to 11) (Barrington 2009 **Level IV**, n=8,189 [PNBs in 6,950 patients]). A large single-institution database identified four cases of peripheral nerve injuries with sensory loss persisting for 6 to 12 mth, which were not able to be attributed to nonblock causes (≈3/10,000) (Orebaugh 2012 **Level IV**, n=14,498 [PNBs]). A single-centre study reported the incidence of postoperative neurologic symptoms

(PONS) >6 mth duration as 9/10,000 (95%CI 5 to 17) (Sites 2012 **Level IV**, n=12,668). Nerve injury may follow surgery independently of nerve block procedures. The baseline risk of nerve injury risk inherent to common elective orthopaedic surgical procedures is now better understood (Neal 2015 **GL**). Awareness of the mechanism, location, and frequency of nerve injuries associated with elective orthopedic surgery may facilitate diagnosis and treatment of peripheral nerve injury. After TKA, the all-cause incidence of perioperative nerve injury was 0.79%; however, this outcome was not associated with PNB (Jacob 2011b **Level III-3**, n=12,329). Similarly, PNB following THA (Jacob 2011a **Level III-3**, n=12,998) and shoulder arthroplasty (Sviggum 2012 **Level III-3**, n=1,569) was not associated with perioperative nerve injury. Observational studies consistently report that PONS or postoperative neurologic dysfunction may be related to patient and surgical factors and that the incidence of neuropathy directly related to peripheral regional anaesthesia is infrequent or rare (Sviggum 2012 **Level III-3**, n=1,569; Jacob 2011a **Level III-3**, n=12,998; Jacob 2011b **Level III-3**, n=12,329; Sites 2012 **Level IV**, n=12,668; Orebaugh 2012 **Level IV**, n=14,498; Barrington 2009 **Level IV**, n=8,189 [PNBs in 6,950 patients]). However, distinguishing between contributing surgical, anaesthetic, and patient factors is often difficult. Differential diagnosis should include use of a pneumatic tourniquet (>120 min), which has been associated with nerve injury. These injuries often present as diffuse sensorimotor deficits. Delaying placement of regional blocks if assessment of postoperative nerve function is important for the surgeon is a consideration. Mechanical, ischaemic or neurotoxic injury of the neuraxis or peripheral nervous system associated with regional anaesthesia and pain medicine interventions has been summarised into a practice advisory (Neal 2015 **GL**).

5.8.11.3 | Local Anaesthetic Systemic Toxicity

US-guidance has been associated with a reduced incidence of local anaesthetic systemic toxicity (LAST) following PNB, with an incidence of 8.7/10,000 PNBs and no related deaths (Barrington 2013 **Level IV**, n=25,336 [PNBs in 20,021 patients]). This result is consistent with an analysis of block outcomes over 10 y period, which revealed higher LAST incidence with landmark vs US-guided technique: 7 of 5,932 vs 0 of 16,858 respectively (Melnyk 2018 **Level IV**, n=22,790 [PNBs]). A review of case reports and registries estimates LAST incidence to be 2.7/10,000 PNBs (95%CI 2.1 to 3.5) (Gitman 2018 **Level IV** n=251,325). Seizure was the most common presenting feature (53% [CRs] and 61% [registries]). It is important to note that presenting features of LAST may not comply with classic descriptions and be overlooked or disguised by perioperative processes and interventions. There is a trend toward delayed presentation, which may mirror the increased use of US-guidance (fewer intravascular injections), local infiltration techniques (slower systemic uptake), and continuous local anaesthetic infusions. Small patient size, sarcopenia and patient co-morbidities potentially increase the risk of LAST. An increasing number of reported events occur outside of the traditional hospital setting and involve non-anaesthetists. Caution must be exercised with all regional techniques as case reports of adverse outcomes, including death, continue to occur (Vadi 2014 **CR** & **NR**), even with local anaesthetic infusion catheters placed under direct vision (Calenda 2014 **CR**). This caution also applies to fascial plane techniques such as TAPB that tend to involve large doses (Hessian 2013 **Level IV PK**, n=20; Griffiths 2013 **Level IV PK**, n=8) (see also Section 4.4.3.2). Of note, an analysis from the Pediatric Regional Anesthesia Network database indicates that TAPB has a low risk of local anaesthetic systemic toxicity in this patient population (Long 2014 **Level IV**, n=19,994).

Treatment of LAST should be directed towards importance of the airway and oxygenation (avoiding hypercarbia and acidosis), seizure control and lipid emulsion therapy (100 mL lipid emulsion 20% for patient 70 kg or over; 1.5 mL/kg for patient less than 70 kg). Mechanisms of lipid emulsion reversal of LAST include rapid partitioning, direct inotropy, and post ischaemic conditioning (Neal 2018a **GL**). The American Society of Regional Anesthesia and Pain Medicine (ASRA) has updated its

checklist for the management of LAST (Neal 2018b **GL**). Exact volume and flow rate of lipid emulsion are not essential; however recommendations include avoiding administration of >10 to 12 mL/kg of lipid emulsion, calling for help early, and use of electronic decision support tools. The pharmacological treatment of LAST is different to other cardiac arrest scenarios. It is recommended to reduce individual doses of adrenaline to less than 100 mcg, avoiding vasopressin, calcium channel blockers, beta-blockers and use of other local anaesthetics. A guideline for management of severe LAST has been developed by the AAGBI and is endorsed by ANZCA (AAGBI 2010 **GL**).

5.8.11.4 | Infection

The strongest recommendations for infection-prevention are effective hand hygiene and skin preparation with alcohol-based chlorhexidine solution; as per the UK epic2 National Guidelines (Pratt 2007 **GL**). These guidelines recommend full barrier precautions for central venous catheter placement (cap, mask, sterile gown and gloves; and large drape). Although specific data for aseptic technique in CPNB is lacking, advisories have been developed which advocate similar practices (Hebl 2011 **NR**). In a review of infections associated with CPNB, the use of full surgical-type aseptic technique for CPNB procedures was supported (Capdevila 2009 **NR**). Identified risk factors for local CPNB catheter inflammation include ICU stay, duration of catheter use >48 h, lack of antibiotic prophylaxis, axillary or femoral location and frequent dressing changes (Capdevila 2009 **NR**). The use of a chlorhexidine-impregnated patch designed to inhibit bacterial growth for days as a dressing after femoral nerve catheter insertion did not reduce the low rate of bacterial colonisation, nor reduce local skin inflammation (2.1 vs 10.6%) in an underpowered RCT (Schroeder 2012 **Level 2**, n=100, JS 3). Chlorhexidine was also the superior skin disinfectant prior to regional catheter insertion vs povidone iodine (Krobbuaban 2011 **Level II**, n=100, JS 4); a positive skin culture immediately after skin disinfection occurred in 10 vs 35% (NNT 4).

The implications of catheter-related sepsis in patients with implanted prosthetic devices (eg joint arthroplasty) are significant and therefore all reasonable measures should be taken to minimise the risk of infection. The widespread use of US-guidance has introduced a potential risk related to contamination. The use of a sterile disposable sheath reduces the risk of contamination of the aseptic field by the transducer. Decontaminating US transducers with 70% isopropyl alcohol was effective at removing pathogenic organisms (Chuan 2013 **Level IV**, n=120 [swabs]).

KEY MESSAGES

1. Topical EMLA® cream (eutectic mixture of lignocaine [lidocaine] and prilocaine) is effective in reducing the pain associated with venous ulcer debridement (**U**) (**Level I** [Cochrane Review]).
2. Transversus abdominis plane blocks provide pain relief superior to local anaesthetic infiltration for a range of abdominal surgeries (**N**) (**Level I** [PRISMA]).
3. Intraperitoneal local anaesthetic instillation after laparoscopic gastric surgery (**N**) (**Level I** [PRISMA]) and laparoscopic cholecystectomy (**U**) (**Level I**) improves postoperative pain outcomes.
4. Adductor canal block results in similar postoperative pain outcomes following total knee arthroplasty versus femoral nerve block with less quadriceps weakness, earlier mobilisation and better functional recovery (**S**) (**Level I** [PRISMA]).
5. Following thoracotomy, thoracic paravertebral block provides comparable analgesia to thoracic epidural analgesia (**U**) (**Level I**).
6. Continuous peripheral nerve block, compared with single-injection peripheral nerve block, results in improved pain control, decreased need for opioid analgesics, reduced nausea and improved patient satisfaction in some settings, in particular in the first 24 hours postoperatively (**W**) (**Level I**).
7. Femoral nerve block, either single-injection or continuous, provides better analgesia and decreased nausea compared with parenteral opioid-based techniques after total knee arthroplasty (**U**) (**Level I**).
8. Compared with opioid analgesia, continuous peripheral nerve block (regardless of catheter location) provides better postoperative analgesia and leads to reductions in opioid use as well as nausea, vomiting, pruritus and sedation (**U**) (**Level I**).
9. Blocks performed using ultrasound guidance are more likely to be successful, faster to perform, with faster onset and longer duration compared with localisation using a peripheral nerve stimulator (**U**) (**Level I**).
10. Morphine injected into the intra-articular space following knee arthroscopy does not improve analgesia compared with placebo (**U**) (**Level I**).
11. Following total knee arthroplasty, local infiltration analgesia reduces postoperative pain for up to 32 hours when compared to systemic analgesics alone; however, there is limited benefit in comparison to femoral nerve block (**U**) (**Level I**).
12. Following total hip arthroplasty, there is no additional analgesic benefit for local infiltration analgesia over conventional multimodal analgesia (**S**) (**Level I**) and peripheral nerve blocks have limited or no effect on postoperative pain (**Q**) (**Level II**).
13. Following either knee or hip arthroplasty, there is insufficient evidence to support postoperative administration of local infiltration analgesia via catheter (**U**) (**Level I**).
14. Local anaesthetic infusions or intermittent injections through wound catheters provide analgesic benefits following gynaecological and obstetric surgery, but not other abdominal or nonorthopaedic surgery (**Q**) (**Level I**).

15. Intraurethral instillation of lignocaine gel provides analgesia during flexible cystoscopy (**U**) (**Level I**).
16. The benefit of routine sciatic nerve block in addition to femoral nerve block for analgesia following total knee joint arthroplasty remains unclear (**U**) (**Level I**).
17. Continuous interscalene analgesia provides better analgesia, reduced opioid-related adverse effects and improved patient satisfaction compared with intravenous PCA or single-injection interscalene block after open shoulder surgery (**U**) (**Level II**).
18. Erector spinae plane blocks provide postoperative analgesia superior to systemic analgesia after cardiac surgery (**N**) (**Level II**) and to transverse abdominus blocks after laparoscopic cholecystectomy (**N**) (**Level II**).
19. Quadratus lumborum block reduces pain scores and opioid requirements following Caesarean section compared to placebo or control (**N**) (**Level II**).
20. Intra-articular bupivacaine infusions have been associated with chondrolysis and their use has been cautioned against (**U**) (**Level IV**).
21. Postoperative neurologic symptoms or dysfunction is often related to patient and surgical factors and the incidence of neuropathy directly related to peripheral regional anaesthesia is rare (**S**) (**Level III-3**).
22. Ultrasound guidance of regional blocks is associated with a reduced risk of local anaesthetic systemic toxicity in adults (**N**) (**Level IV**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Continuous peripheral nerve blocks carry a risk of infection; skin preparation with alcohol-based chlorhexidine and full barrier precautions (including face masks) are recommended for insertion of peripheral nerve catheters (**U**).

☑ Ultrasound-guided techniques should be practiced with a high degree of skill and care, including aseptic techniques, as they do not eliminate the risks of injury to tissues and structures, local anaesthetic systemic toxicity or site contamination (**U**).

☑ Caution should be used when considering and performing some peripheral nerve or plexus blocks in patients with impaired coagulation, in particular where the PNB is performed at a deep location that prevents external compression, should bleeding occur (**N**).

5.9 | Regional analgesia and concurrent anticoagulant medications

5.9.1 | Neuraxial block and anticoagulant medication

The low event rate of epidural haematoma means that evidence cannot be based on RCTs but must rely on data from case reports, case series and large audits. An American Society of Regional Anesthesia and Pain Medicine (ASRA) Practice Advisory publication provides a good overview of and guidance on neurological complications of regional anaesthesia (Neal 2008 **GL**).

The population incidence of epidural haematoma following neuraxial block is possibly smaller than that of spontaneous epidural haematoma, however the rate in patients exposed to epidural anaesthesia is more appropriate for comparison. Between 1962 and 1992, 326 case reports of spontaneous epidural haematoma were published (Schmidt 1992 **Level IV**), while between 1906 and 1996 only 51 cases of epidural haematoma following epidural anaesthesia or analgesia were reported (Wulf 1996 **Level IV**).

Anticoagulation (present in 48% of cases) was the most important risk factor for epidural haematoma following insertion of an epidural needle/catheter, followed by coagulopathy (present in 38% of cases) (Wulf 1996 **Level IV**, n=51). This was confirmed by the series of epidural haematomas that followed epidural anaesthesia/analgesia in combination with inappropriate LMWH regimens in the USA, where the incidence was reported to be 1 in 3,000 (Horlocker 2003 **Level IV**).

In view of the increased risk with anticoagulation, ASRA (Horlocker 2010 **GL**) and the European Society of Anaesthesiology (ESA) (Gogarten 2010 **GL**) published a number of consensus statements and recommendations on regional anaesthesia in patients receiving antithrombotic or thrombolytic therapy. Such statements should be viewed as "*a panel of experts*" best faith efforts to offer reasonable pathways to provide safe and quality patient care while allowing for clinical differences based on individual situations (Bergqvist 2003 **NR**). It is recognised that variances from recommendations outlined in the ASRA guidelines "*may be acceptable based on the judgement of the responsible anesthesiologist*" (Horlocker 2010 **GL**). That is, these guidelines will not substitute for an individual risk/benefit assessment of every patient by the individual anaesthetist.

The ASRA guideline was updated in 2018 (Horlocker 2018 **GL**), but the ESA (Gogarten 2010 **GL**) recommendations have not been updated since 2010, despite the fact that new information on both established and newly introduced anticoagulants has become available. Subsequent guidelines developed for interventional spine and pain procedures jointly by ASRA, European Society of Regional Anaesthesia and Pain Therapy (ESRA), the American Academy of Pain Medicine (AAPM), the International Neuromodulation Society (IMS), the North American Neuromodulation Society and the World Institute of Pain (WIP) in 2015 (Narouze 2015 **GL**) were updated in 2018 (Narouze 2018 **GL**). These guidelines classify pain procedures according to potential risk of serious bleeding and emphasise the importance of assessing both procedure and patient-specific risk factors, such that concurrent use of anticoagulant or antiplatelet agents increases the potential procedural risk.

The Society for Obstetric Anesthesia and Perinatalogy (SOAP) published a consensus statement in 2018 also (Leffert 2018 **GL**), in the context of increased use of thromboprophylaxis in obstetrics and differences in pharmacokinetics of anticoagulants in the obstetric population, as well as the competing risks to the fetus and from general anaesthesia, which were issues not directly addressed in the aforementioned guidelines.

Table 5.2 summarises recommendations from these guidelines for timing of antithrombotic or antifibrinolytic administration in relation to neuraxial blockade including epidural catheter insertion and removal.

Recommendations aim to minimise anticoagulant presence during both insertion and removal of an epidural catheter due to associated risk of spinal haematoma formation. Time intervals between discontinuation of therapeutic anticoagulation and neuraxial block are predominantly pharmacologically based. After 5 half-lives (adjusted for renal impairment, if the anticoagulant is renally excreted), the residual anticoagulant activity will be 3%. Prophylactic doses of parenteral anticoagulants are interrupted for 2 half-lives due to lower levels of anticoagulation, although this may not be the case for non-vitamin K oral anticoagulants (NOACs) as discussed below.

Time intervals for subsequent dosing are based on the time to reach peak effect for each anticoagulant which is subtracted from the 8 h required for platelet plug stabilisation (Rosencher 2007 **GL**; Bouma 2006 **NR BS**).

Pregnancy-related physiological changes may impact unfractionated heparin (UFH) and/or LMWH pharmacokinetics. Increased maternal plasma volume may increase their volume of distribution with decreased peak and steady-state concentrations, more rapid renal clearance due to increased blood flow and glomerular filtration rate (GFR) and the free fraction of highly protein bound drugs may be increased due to lower serum albumin concentration in pregnancy (Leffert 2018 **GL**). Consequently, recommendations for the range of drug doses, including intermediate and high doses have been included in the SOAP guideline and Table 5.2.

For some anticoagulants there is a role for coagulation studies and use of anticoagulant reversal agents may be relevant if urgent neuraxial block is required.

- *Unfractionated heparin SC or IV*— Thromboprophylaxis with SC UFH given twice-daily is not a contraindication to neuraxial block after an appropriate time interval (see Table 5.2). IV UFH administration results in immediate anticoagulant activity. SC administration has lower bioavailability than IV UFH administration with a 1 to 2 h delay in onset of anticoagulant activity. Offset of action is also slower when higher SC doses are used. To identify heparin-induced thrombocytopenia (HIT), a platelet count should be checked during therapy continued for more than 5 d and specifically prior to removal of an epidural catheter in patients who have had more than 4 d of heparin therapy. In patients with prior heparin exposure, pre-formed heparin-platelet factor 4 antibodies may exist and the onset of HIT may occur by 2 d. The anticoagulant activity of unfractionated heparin, administered IV or SC can be fully reversed with protamine (1 mg per 100 IU heparin, max dose 50 mg).
- *Low molecular weight heparin* — Routine use of anti-Xa monitoring is not recommended and a safe level of residual anti-Xa activity for neuraxial block has not been determined. Concurrent administration of other medicines that may affect haemostasis (eg antiplatelet medicines) should be avoided. Renal impairment prolongs the effect of LMWH (for dosing recommendations in renal impairment see Table 5.3), although only one of the guidelines suggests determination of antifactor Xa activity in patients with renal insufficiency (Narouze 2015 **GL**). Protamine reverses approximately 60% of LMWH activity.
- *Fondaparinux* – This parenteral synthetic pentasaccharide with antiXa activity has a plasma half-life of 21 h and is not reversed by protamine. Neuraxial anaesthesia is not recommended outside of the context of clinical trials and an alternative VTE prophylactic agent should be utilised (Horlocker 2018 **GL**).
- *Oral warfarin* — Established warfarin therapy should be discontinued 5 d prior to neuraxial block and the INR normalised. Preoperative initiation of warfarin therapy requires an INR check prior to neuraxial block if a single dose of warfarin 5 mg was given >24 h preoperatively or a second dose was given. The INR should also be checked prior to

removal of indwelling epidural catheters if warfarin was administered >36 h before. An INR <1.5 is estimated to be a safe level for removal, while an INR >3 requires withholding warfarin and waiting for normalisation or actively reversing warfarin to allow earlier catheter removal. Specific advice on warfarin reversal is available in an updated Australian and New Zealand guideline (Tran 2013 **GL**).

Non-vitamin K oral anticoagulants (NOACs)

Neuraxial techniques should be avoided whilst patients are anticoagulated with NOACs.

- *Rivaroxaban* and *apixaban* are oral direct factor Xa inhibitors with partial renal excretion. They require cessation at least 3 d prior to neuraxial blockade (see Table 5.2 for details) and may be recommenced 6 h post epidural catheter removal or at least 24 h post-surgery. Andexanet alpha partly reversed the anti-Xa activity of these agents in patients with major bleeding but is not currently available for use in Australia or New Zealand and has not been trialled in a surgical or procedural setting (Connolly 2019 **Level IV**, n=352).
- *Dabigatran* is an oral direct thrombin inhibitor with 80% renal clearance. It also requires cessation at least 3 d prior to neuraxial anaesthesia and longer periods of interruption for various degrees of renal impairment and it may be recommenced 6 h post epidural catheter removal or at least 24 h post-surgery. Idarucizumab is a direct specific reversal agent for dabigatran and is widely available in Australia and New Zealand. A 5 g dose rapidly and completely reverses dabigatran in patients with major bleeding and 92% patients requiring urgent surgery or procedures had normal haemostasis post administration of idarucizumab including some patients requiring urgent neuraxial anaesthesia (Pollack 2017 **Level III-1**, n=503). A dilute thrombin time assay can quantify the dabigatran concentration in plasma and should be tested 24 h after administration of idarucizumab as a minority of patients may show rising dabigatran concentrations potentially requiring a further dose of idarucizumab.
- The timing of NOAC interruption was standardised for the particular anticoagulant, renal function and surgical bleeding risk (Douketis 2019 **Level III-2**, n=3,007). Patients did not receive bridging anticoagulation. Rates of major bleeding (2%) and arterial thromboembolism (<1%) were low. A subgroup of 230 patients received neuraxial anaesthesia and were managed according to the 'high-bleeding risk' protocol in which patients received their last NOAC dose 3 d prior to surgery or 5 d prior for patients on dabigatran with creatinine clearance less than 50 mL/min. Almost all patients (98.8%) had a residual anticoagulant level less than 50 ng/mL. The proportion of these patients with residual anticoagulant level less than 30 ng/mL was 93.1% in the apixaban cohort, 98.9% in the dabigatran cohort and 85.4% in the rivaroxaban cohort. The optimal preoperative anticoagulant level has not been established and some assays show increased result variability below 50 ng/mL. No spinal haematomas were reported in this study. The same NOAC interruption protocol was used for different doses of each NOAC and there was no significant difference in drug levels preoperatively. NOACs have a wide therapeutic index and consequently shorter periods of interruption are not currently recommended for the lower drug doses.

Antiplatelet medications

NsNSAIDs and other antiplatelet therapies

NsNSAIDs including aspirin alone do not significantly increase the risk of spinal haematoma but should be regarded as a risk factor if combined with other classes of anticoagulants. In such situations, coxibs should be preferred. Recommended time intervals between discontinuation or recommencement of nsNSAIDs and other antiplatelet medications (eg prasugrel) and neuraxial

block are given in Table 5.2. There are significant changes in the updated guidelines with wide variation in recommendations for different agents. For some agents, the post-operative time interval to recommencement is longer than the recommendation for neuraxial procedures without surgery.

Herbal therapy

Although garlic (*Allium sativum*), ginkgo (*Ginkgo biloba*), ginseng (*Panax* spp), dong quai (*Angelica sinensis*) and danshen (*Salvia miltiorrhiza*) have effects on haemostasis, there are currently no specific concerns about their use alone with neuraxial block. However, their combination with other anticoagulants or antithrombotics increases the risks. Patients taking dong quai and danshen combined with warfarin require an INR check.

Fibrinolytics and thrombolytics

Patients receiving fibrinolytic or thrombolytic medicines should not undergo neuraxial block except in exceptional circumstances; no data are available on a safe time interval after use of such medicines but at least 48 h and normalisation of fibrinogen level are recommended. No definite recommendations are given for the removal of neuraxial catheters after initiation of such therapy, although fibrinogen level might be a useful guide in such situations.

5.9.2 | Plexus and other peripheral regional block and anticoagulant medication

Significant blood loss or haematoma formation, rather than neurological deficit, seems to be the main risk when plexus or other regional blocks are performed in patients taking anticoagulant medications (Horlocker 2010 **GL**). Technical and anatomical considerations are different for pain interventions with both patient-specific and procedure-specific risk factors requiring assessment (Narouze 2018 **GL**).

In a series of peripheral nerve blocks for joint replacement (continuous lumbar plexus, continuous femoral and continuous or single sciatic block), with removal of the catheters at POD 2 or 3, no perineural haematoma was found despite use of warfarin (50.0%), fondaparinux (12.8%), dalteparin (11.6%), enoxaparin (1.8%) and aspirin (23.8%) (Chelly 2008a **Level IV**, n=6,935). A case series of patients receiving rivaroxaban 10 mg with a femoral catheter for TKA replacement *in situ* and removal 20 h after intake reported no cases of haematoma formation (Idestrup 2014 **Level IV**, n=504). However, a case series of bleeding complications after removal of femoral and sciatic catheters under LMWH suggests that caution is appropriate (Bickler 2006 **Level IV**, n=3; Horlocker 2010 **GL**).

For obvious reasons, deep blocks may be more at risk of bleeding complications than superficial blocks, where external compression is possible. Case reports of retroperitoneal haematoma after lumbar plexus block in conjunction with anticoagulation are published with either no neurological sequelae (Weller 2003 **CR**) or plexopathy (Klein 1997 **CR**). However, in a case series where lumbar plexus catheters were removed in warfarinised patients (36.2% with an INR >1.4 [range 1.5–3.9]), only one superficial bleeding event occurred (in a patient with INR 3.0) (Chelly 2008b **Level IV**, n=670).

The updated guidelines developed for interventional spine and pain procedures classify procedure–related risks, then upgrade the risk for patients on anticoagulants such that preoperative recommendations are similar to other guidelines but the post-operative resumption of anticoagulants is aligned with postsurgical recommendations of at least 24 h delay (Narouze 2018 **GL**). An expert panel of the Regional Anesthesia and Acute Pain Section of the Canadian Anesthesiologists Society (CAS) published a practice advisory on the bleeding risks for peripheral nerve and interfascial plane blockade, which categorises blocks into low, moderate and high risk (Tsui 2019b **GL**).

KEY MESSAGES

1. Anticoagulation and coagulopathy are the two most important risk factors for the development of epidural haematoma after neuraxial block (**U**) (**Level IV**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Consensus statements of experts guide the timing and choice of regional anaesthesia and analgesia in the context of anticoagulation but do not represent a standard of care and will not substitute the risk/benefit assessment of the individual patient by the individual anaesthetist (**S**).

☑ Caution should be used when considering and performing some peripheral nerve or plexus blocks in patients with impaired coagulation, in particular where the peripheral nerve block is performed at a deep location that prevents external compression, should bleeding occur (**S**).

TABLE 5.2 | Recommendations for timing of antithrombotic or antifibrinolytic administration in relation to neuraxial blockade

Medication	Dosing	Before epidural insertion	Whilst epidural catheter in place	Prior to epidural catheter removal	After epidural catheter removal
		Minimum time after last anticoagulant or thrombotic/thrombolytic dose until insertion	Delay from epidural insertion until next anticoagulant or thrombotic/ thrombolytic dose	**Minimum** time after last anticoagulant or thrombotic/thrombolytic dose until removal of epidural catheter	**Minimum** time after epidural catheter removal and next dose of anticoagulant or thrombotic/thrombolytic dose
Unfractionated heparin subcutaneous	prophylactic, up to 15000 IU/d	4-6 h or ensure normal APTT	1 h	4-6 h	1 h
Unfractionated heparin subcutaneous	intermediate, >15000 IU/d up to 20000 IU/d	12 h* AND ensure APTT normal	Safety of higher doses not established. Assess individual risks and benefits	12 h* AND ensure APTT normal	1 h
Unfractionated heparin subcutaneous	therapeutic (full dose), > 20000 IU/d s/c	24 h* AND ensure APTT normal	Safety of higher doses not established. Assess individual risks and benefits	24 h* AND ensure APTT normal	1 h
Unfractionated heparin intravenous (IV) infusion	therapeutic (full dose), IV	Discontinue infusion for 4-6 h AND ensure normal APTT	1 h (Wait 24 h if bloody tap)	4-6 h	1-2 h
LMWH (Low molecular weight heparin) Eg: enoxaparin (Clexane®), dalteparin (Fragmin®) subcutaneous	prophylactic (dosing adjusted to renal function see Table 5.3)	12 h	12 h	12 h	4 h
LMWH	therapeutic (full dose)	24 h	12 h	24 h	4 h**
Fondaparinux (Arixtra®) subcutaneous	prophylactic	2 d (longer if higher doses used)	CONTRAINDICATED	CONTRAINDICATED	6 h
Warfarin	therapeutic (full dose)	5 d AND ensure INR < 1.5	CONTRAINDICATED	INR < 1.5	4 h
Apixaban (Eliquis®)	2.5mg BD or 5mg BD				
CrCl > 50 ml/min		3 d	CONTRAINDICATED	CONTRAINDICATED	At least 6 h
CrCl 25-50 ml/min		3 d	CONTRAINDICATED	CONTRAINDICATED	At least 6 h
CrCl < 25 ml/min		Seek specialist advice with haematologist. Drug levels can be measured to assist in decision making.	CONTRAINDICATED	CONTRAINDICATED	CONTRAINDICATED
Rivaroxaban (Xarelto®)	15 or 20mg daily				
CrCl > 50 ml/min		3 d	CONTRAINDICATED	CONTRAINDICATED	At least 6 h
CrCl 30-50 ml/min		3 d	CONTRAINDICATED	CONTRAINDICATED	At least 6 h
CrCl < 30 ml/min		Seek specialist advice with haematologist. Drug levels can be measured to assist in decision making.	CONTRAINDICATED	CONTRAINDICATED	CONTRAINDICATED
Dabigatran (Pradaxa®)					
CrCl > 80 ml/min		3 d	CONTRAINDICATED	CONTRAINDICATED	At least 6 h
CrCl 50-80 ml/min		4 d	CONTRAINDICATED	CONTRAINDICATED	At least 6 h
CrCl 30-49 ml/min		5 d	CONTRAINDICATED	CONTRAINDICATED	At least 6 h
CrCl < 30 ml/min		Seek specialist advice with haematologist. Drug levels can be measured to assist in decision making.	CONTRAINDICATED	CONTRAINDICATED	CONTRAINDICATED
Thrombolytic therapy eg: tissue plasminogen activator tpA		At least 48 h and ensure normal coagulation studies	CONTRAINDICATED	CONTRAINDICATED	If thrombolytics required, check that no lumbar puncture, epidural or spinal anaesthesia in the preceding 10 d

Medication	Dosing	Before epidural insertion	Whilst epidural catheter in place	Prior to epidural catheter removal	After epidural catheter removal
Non-steroidal anti-inflammatory drugs (NSAIDS)	Interruption not required unless combined with other antithrombotics	COX-2 agents have minimal effect on platelet function			
Aspirin (COX inhibitor)	Interruption not required unless combined with other antithrombotics				
Thienopyridines (Inhibition of ADP-induced platelet aggregation)					
Ticlopidine		10 d	May be used without loading dose		6 h if loading dose given, or post-operatively 24 h
Clopidogrel		5-7 d	May be used without loading dose		6 h if loading dose given, or post-operatively 24 h
Prasugrel		7-10 d	CONTRAINDICATED due to rapid onset of action	CONTRAINDICATED	6 h if loading dose given, or post-operatively 24 h
Direct and reversible P2Y12 receptor inhibitors: Ticagrelor		5-7 d	CONTRAINDICATED due to rapid onset of action	CONTRAINDICATED	6 h if loading dose given, or post-operatively 24 h
Direct and reversible P2Y12 receptor inhibitors: Cangrelor		3 h	CONTRAINDICATED due to rapid onset of action	CONTRAINDICATED	8 h
Glycoprotein IIb/IIIa Inhibitors: Abciximab		24-48 h	CONTRAINDICATED due to rapid onset of action	CONTRAINDICATED	4 weeks post-surgery, if emergent use required minimise sensory and motor block to facilitate assessment of neurological function
Eptifibatide, Tirofiban		4-8 h	CONTRAINDICATED due to rapid onset of action	CONTRAINDICATED	4 weeks post-surgery, if emergent use required minimise sensory and motor block to facilitate assessment of neurological function
Selective inhibition of PDE IIIA: Cilostazol		2 d	CONTRAINDICATED	CONTRAINDICATED	6 h post catheter removal or post-operatively 24 h
Dipyridamole	Potential risk in combination with aspirin	24 h (for extended release formulations)			
Selective serotonin re-uptake inhibitors (SSRIs) - antidepressants with inhibition of serotonin-mediated plateletr aggregation	Low risk unless associated with other patient specific risk factors or combined with other antithrombotics	Consider discontinuation or switch to alternative agent			

** SC UFH - delayed excretion with higher doses administered by this route*
*** For post-operative therapeutic LMWH dosing, commencement should be at least 24 h post-surgery with low bleeding risk and 48-72 h post-surgery with high-bleeding risk*

Table 5.3 | Dosing of prophylactic LMWH in renal impairment

Normal dosing (CrCl greater than 30 mL / min)	Renal impairment (CrCl =10 to 30 mL / min)	Renal impairment (CrCl less than 10 mL / min)
TWICE a day regimen: Enoxaparin (Clexane®): 1 mg / kg TWICE a day (max. 150 mg TWICE a day Dalteparin (Fragmin®): 100 units / kg / TWICE a day (max. 15,000 units TWICE a day)	Enoxaparin (Clexane®)*: 1 mg / kg ONCE daily Dalteparin (Fragmin®)*: 100 units / kg ONCEdaily	Use unfractionated heparin
ONCE daily regimen: Enoxaparin (Clexane®): 1.5 mg / kg ONCE daily (max. 180 mg ONCE daily) Dalteparin (Fragmin®): 200 units / kg ONCE daily (max. 25,000 units ONCE daily)		

*The determination of an tiXa levels is recommended for optimal dosing

Patient-controlled analgesia

Section Editor:
Dr Richard Halliwell

Contributor: Dr Richard Halliwell

6.0 | Patient-controlled analgesia

Patient-controlled analgesia (PCA) refers to all methods of pain relief that allow a patient to self-administer small doses of an analgesic agent as required. Most often, the term PCA refers to programmable infusion pumps that deliver opioid medications IV. However, many other methods and routes of delivery using opioids as well as other analgesic agents have been described (SC, epidural, IT, SL, IN, oral, pulmonary, and TD). In addition to treating postoperative pain, PCA is used for pain following trauma and with cancer.

For epidural PCA see Section 5.6.3; for PCA use in labour see Section 9.1.3.1 and in children see Sections 10.5.2 to 10.5.4.

6.1 | Efficacy of intravenous PCA

6.1.1 | Analgesia, patient preference and outcomes

An updated Cochrane review is published (McNicol 2015 **Level I** [Cochrane], 49 RCTs, n=3,412); this includes only four RCTs since 2005, which may reflect the adoption of PCA into usual clinical practice. The meta-analysis compares IV PCA using full mu-opioids with intermittent full mu-opioids (usually IM morphine), and also includes the use of supplemental NSAIDs or paracetamol. The most frequently used opioid is morphine (33/49 RCTs); the most common bolus size is 1 mg and the most common lockout intervals are 5 to 10 min. There was a lack of head-to-head trials comparing different opioids via PCA so no comparison of opioids could be made. IV opioid by PCA for treatment of postoperative pain provides better analgesia than conventional (IM, SC) opioid regimens, although the magnitude of the difference in analgesia is small (MD 9.7/100; 95%CI 12.5 to 7 [0 to 48 h]). PCA use increases opioid consumption at 0 to 24 h (7 MME; 95%CI 1.4 to 13) and 25 to 48 h (5 MME; 95%CI 3 to 8). PCA improves number of patients satisfied (80% vs 61) (RR 1.32; 95%CI 1.12 to 1.53) (11 RCTs, n= 547) and satisfaction scores (SMD 0.55; 95%CI 0.13 to 0.97) (7 RCTs, n=427). This benefit may relate to the increased autonomy that PCA confers. None of the studies measured 'readiness for discharge'. LOS does not differ (10 RCTs), but this outcome may have been dependent on other factors. Serious adverse event rates (including death, wound infections, atelectasis and adhesions) do not differ between the two groups (19 RCTs, n=1,284). However, as death is a rare event, larger patient numbers are required to reliably evaluate this outcome. Other adverse events occur similarly: sedation (15 vs 16%), respiratory depression (Sa02 ≤ 90% or RR <10/min or need for naloxone) (2.3 vs 2%) and nausea and/or vomiting (30 vs 32%), while pruritus was more frequent in the PCA group (15 vs 8%) (RR 1.8; 95%CI 1.1 to 2.8).

In an ED setting, IV PCA was as effective as nurse-administered IV bolus doses of opioid (Evans 2005 **Level II**, n=86, JS 3). In two other RCTs in the ED setting, PCA morphine provided more effective analgesia with more rapid onset and higher patient satisfaction than nurse-administered IV morphine (Rahman 2012 **Level II**, n=96, JS 3; Birnbaum 2012 **Level II**, n=211, JS 3).

Other information obtained from published RCTs as well as cohort studies, case-controlled studies and audit reports suggests that IV PCA may be appreciably more effective than intermittent IM opioid analgesia in a "real world" clinical setting; patients given IM opioid analgesia were more than twice as likely to experience moderate to severe pain and severe pain than those given PCA (Dolin 2002 **Level IV SR**, 165 studies, n≈20,000).

In settings where there are high nurse:patient ratios and where it might be easier to provide analgesia truly on-demand, conventional forms of opioid administration may be as effective as IV PCA. A comparison of PCA vs nurse-administered analgesia following cardiac surgery found no difference in analgesia at 24 h (a period when nursing attention is likely to be higher) but significantly better pain relief with PCA at 48 h (Bainbridge 2006 **Level I**, 10 RCTs, n=666).

The enormous variability in PCA parameters (bolus doses, lockout intervals and maximum permitted cumulative doses) used in many studies indicates uncertainty as to the ideal PCA program and may limit the flexibility, and thus the efficacy, of the technique. Individual PCA prescriptions may need to be adjusted if patients are to receive the maximal benefit (Macintyre 2015 **NR**; Macintyre 2008 **NR**; Macintyre 2005 **NR**).

A number of studies have shown that PCA provides less effective pain relief vs epidural analgesia. See Section 5.6.1.1 .

6.2 | Cost of PCA

The use of any analgesic technique, even if it is known to provide more effective pain relief, requires consideration of the cost involved. There is limited data on the economic assessment of PCA vs conventional opioid analgesic techniques; information that is available often does not include the full scope of costs (eg cost of adverse effects or failure of an analgesic technique, as well as the more obvious costs of pumps, disposables and nursing time). However, in general, PCA comes at a higher cost because of the equipment, consumables and medicine preparation; nursing time needed is much less (Chang 2004 **Level II**, n=125, JS 3; Choiniere 1998 **Level II**, n=126, JS 3; Rittenhouse 1999 **Level III-2**; Jacox 1997 **NR**). PCA was more cost-effective than epidural analgesia after major abdominal surgery (LOS and morbidity excluded) (Bartha 2006 **Level III-2**, n=644). In a subsequent assessment, PCA costs were estimated by analysis of a large administrative database covering 500 USA hospitals (Palmer 2014 **Level III-3**, n=11,805,513). The direct and indirect cost estimates (US$ in 2012) were assessed for the first 48 h after major surgery (TKA, THA and open abdominal procedures). The cost estimates range from US$196 to 243 per patient. Further estimates, adding in the costs of adverse effects of PCA programming errors, phlebitis and bacteraemia due to IV access, increased the costs to US$342 to 389 per patient. See also Section 3.3.

6.3 | Medicines used for parenteral PCA

6.3.1 | Opioids

In general, there is little evidence, on a population basis, to suggest that there are any major differences in efficacy or the incidence of adverse effects between morphine and other opioids commonly used in PCA, although the results of individual studies are inconsistent (for more details see 6.3.1.10 below). Most studies are not powered adequately to make conclusions about comparative safety, especially for respiratory depression.

On an individual patient basis, one opioid may be better tolerated than another and a change to an alternative opioid may be beneficial if the patient is experiencing intolerable adverse effects (Woodhouse 1999 **Level II**, n=82 [cross over], JS 4).

6.3.1.1 | Morphine

Morphine is still a commonly used opioid for IV PCA (Palmer 2014 **Level III-2**, n=11,805,513). Compared with other opioids, morphine has a long equilibration half-life between plasma and the CNS effect site (2 to 3 h) (Aubrun 2012 **NR**; Lötsch 2005 **NR**). Furthermore, morphine has an active metabolite, M6G, which has opioid effects, with an equilibration half-life of 7 h and a long elimination half-life (Lötsch 2005 **NR**). Simulated peak effect-site concentration for morphine occurs 8 to 24 h after the commencement of PCA (Sam 2011 **Level III-3 PK**, n=10). These pharmacokinetic features may make morphine less suitable for IV PCA use than other opioids. Limited clinical data suggest that morphine may have a higher incidence of sedation and respiratory depression than fentanyl (Hutchison 2006 **Level III-2**, n=241).

6.3.1.2 | Fentanyl

In general, there is limited evidence to show a difference between morphine and fentanyl in terms of pain relief or the incidence of most adverse effects (Woodhouse 1996 **Level II**, n=50, JS 5; Howell 1995 **Level II**, n=37, JS 3); pruritus was more common with morphine (Woodhouse 1996 **Level II**, n=50, JS 5). A retrospective cohort study of patients having hip or knee surgery found those receiving PCA fentanyl, when compared with morphine or hydromorphone, had lower pain scores and fewer opioid-related adverse effects (PONV, sedation, pruritus or urinary retention) (Hutchison 2006 **Level III-2**, n=241). Fentanyl PCA vs morphine PCA after cardiac surgery had a lower incidence of nausea (32 vs 52%) (Gurbet 2004 **Level II**, n=75, JS 3).

6.3.1.3 | Tramadol

Tramadol by IV PCA has similar analgesic efficacy vs other opioids by IV PCA, mainly vs morphine (7 RCTs) (Murphy 2010 **Level I**, 12 RCTs, n=782). However, the adverse-effect profile is different with the tramadol group experiencing more PONV (OR 1.52; 95%CI 1.07 to 2.14) but less pruritus (OR 0.43; 95%CI 0.19 to 0.98). There was no difference in sedation or fatigue. Data were insufficient to assess safety**.** Tramadol also has a lower risk of respiratory depression and less effect on gastrointestinal motor function compared with other opioids. See also Section 4.1.1.2.

6.3.1.4 | Hydromorphone

There is limited data examining the use of hydromorphone when delivered by IV PCA. A survey of a large USA inpatient database found that hydromorphone was the second most commonly used opioid for PCA after morphine (Palmer 2014 **Level IV**, n=11,805,513). When compared with morphine in patients having general surgery, there was no difference in adverse effects, pain relief or satisfaction (Hong 2008 **Level II**, n=50, JS 4). Hydromorphone and morphine IV PCA had similar rates of opioid-induced adverse effects, with fentanyl having the lowest in a retrospective comparison of patients after hip or knee surgery (Hutchison 2006 **Level III-2**, n=254). In a comparison of IV PCA morphine with hydromorphone in patients having open abdominal surgery, analgesia was equivalent and there were similar adverse effects (Rapp 1996 **Level II**, n=61, JS 3). The morphine group had less cognitive impairment and the hydromorphone group had better mood. A study of patients having IV PCA for oral mucositis pain after bone marrow transplantation found that hydromorphone vs morphine was equally effective for analgesia but hydromorphone had more frequent adverse effects (Coda 1997 **Level II**, n=119, JS 4). Comparing PCA hydromorphone with PCA sufentanil in patients having surgery for colorectal cancer found that postoperative mood assessment differed, with ‘anger’ being lower in the hydromorphone

group (Yang 2018 **Level II**, n=80, JS 5). This may be due to differences in opioid receptor type affinity.

Safety issues have occurred due to confusion about the name of the medicine and its high potency (5 times that of morphine) (NSW Health 2011 **GL**). See also Section 9.5.5.

6.3.1.5 | Oxycodone

Oxycodone, unlike morphine, has a rapid equilibration with the CNS which might make it more suited to PCA use (Sadiq 2013 **BS** & **PK** [rodent]). Oxycodone IV PCA vs morphine IV PCA resulted in similar pain relief and adverse effects during the first 24 h after surgery (breast or spinal) (Silvasti 1998 **Level II,** n=50, JS 3). The dose requirements were similar. After laparoscopic hysterectomy, IV PCA oxycodone dose requirements were lower than with morphine (Lenz 2009 **Level II**, n=91, JS 4) with less sedation in the oxycodone group; pain scores were lower but only in the first h after surgery and thereafter were similar. After maxillofacial surgery, IV PCA oxycodone vs IV PCA tramadol provided equivalent analgesia (Silvasti 1999 **Level II**, n=54, JS 3).

In patients having laparoscopic gynaecological surgery, IV PCA oxycodone and PCA fentanyl produced equivalent analgesia and satisfaction. Dizziness was more common in the oxycodone group, whilst nausea and vomiting were the same (Park 2015 **Level II**, n=74, JS 4). In laparoscopic hysterectomy patients (who received ketorolac and ramosetron), IV PCA oxycodone improved pain relief vs PCA fentanyl, but increased adverse effects of PONV, dizziness, and drowsiness (Kim 2017 **Level II**, n=130, JS 5).

Trials to date are not adequate in sample size to assess if IV PCA oxycodone confers superiority over other opioids.

6.3.1.6 | Pethidine

Compared with morphine, IV PCA pethidine (meperidine) may lead to less effective pain relief on movement (Plummer 1997 **Level II**, n=102, JS 4; Sinatra 1989b **Level II**, n=75, JS 4; Bahar 1985 **Level II**, n=48, JS 1), no difference in nausea and vomiting (Plummer 1997 **Level II**, n=102, JS 4; Woodhouse 1996 **Level II**, n=50, JS 5; Stanley 1996 **Level II**, n=40, JS 5; Bahar 1985 **Level II**, n=48, JS 1) and less sedation (Sinatra 1989a **Level II**, n=75, JS 4) and pruritus (Woodhouse 1996 **Level II**, n=50, JS 5; Sinatra 1989b **Level II**, n=75, JS 4). IV PCA pethidine may cause more cognitive impairment than morphine (Plummer 1997 **Level II**, n=102, JS 4). Pethidine has a neurotoxic metabolite (norpethidine) that can accumulate during PCA administration and can cause adverse effects (Simopoulos 2002 **Level IV**, n=355; Stone 1993 **Level IV**, n=3; McHugh 1999 **NR**).

6.3.1.7 | Methadone

Methadone by IV PCA, in comparison to morphine, provided more effective pain relief at rest and during movement for the first 24 h after surgery, with no difference in adverse effects (Neto 2014 **Level II,** n=34 [trial discontinued prematurely], JS 4). It should be noted, that the pharmacokinetics of methadone are complex (and are not suited to IV PCA use in acute pain management) (Weschules 2008 **NR**). (See also Section 4.3.1.2)

6.3.1.8 | Other opioids

Remifentanil IV PCA provided at least equivalent analgesia vs morphine or fentanyl PCA and may be associated with less nausea and vomiting (Kucukemre 2005 **Level II**, n=69, JS 4; Gurbet 2004 **Level II**, n=75, JS 3). See also Section 9.1.3.1 for discussion of use of IV PCA remifentanil during labour.

6.3.1.9 | Opioid combinations

The combination of two opioids in the PCA syringe has been investigated.

There was no difference in pain scores and adverse effects between fentanyl/morphine and fentanyl by PCA, apart from slightly less nausea with the combination (Friedman 2008 **Level II**, n=64, JS 5).

Beneficial effects on pain relief and the incidence of pruritus in a comparison of morphine, nalbuphine and varying combinations of the two medicines were dependent on the ratio of medicines used (Yeh 2007 **Level II**, n=311, JS 5). The combination, when compared to morphine alone, provided improved analgesia and reduced nausea.

The combination of alfentanil/morphine IV PCA resulted in no differences in pain relief or adverse effects vs morphine alone, although patients who received alfentanil/morphine rated speed of onset and adequacy of analgesia as better (Ngan Kee 1999 **Level II**, n=80, JS 5). There was no improvement in pain-related sleep disturbance with this combination vs fentanyl alone but analgesia, both at rest and movement, was better in the first 24 h after surgery (Lee 2013 **Level II**, n=212, JS 5).

Compared with IV PCA tramadol alone, remifentanil added to tramadol improved pain relief but increased total opioid doses used (Unlugenc 2008 **Level II**, n=62, JS 4).

6.3.2 | Adverse effects of PCA opioids

As noted in Section 6.1.1 above, meta-analyses and individual studies have shown that, in general, the risk of adverse effects is similar for all opioids administered by PCA, regardless of the opioid used. However, individual patients may be intolerant of specific opioids but tolerant of others (Woodhouse 1999 **Level II**, n=82 [cross over], JS 4). In a network meta-analysis, adverse effects occur at differing frequencies for the various opioids at equianalgesic doses (Dinges 2019 **Level I** [NMA], 63 RCTs, n unspecified). Results are reported as a relative risk (with morphine as the comparator):

- Nausea and vomiting are most frequent with buprenorphine (RR 1.37; 95%CI 1.05 to 1.8) and least with fentanyl (RR 0.82; 95%CI 0.67 to 1.0). Other opioids are not different to morphine (39 RCTs, n=4,614);
- Pruritus is the most frequent with morphine, and the least frequent with methadone (RR 0.17; 95%CI 0.03 to 0.90) and pethidine (RR 0.47; 95%CI 0.25 to 0.87). Other opioids (including oxycodone, tramadol, fentanyl, hydromorphone and remifentanil) are not significantly different to morphine (39 RCTs, n=3,480);
- Sedation is least frequent with fentanyl, oxymorphone and pethidine. Other opioids are not different to morphine (31 RCTs, n=1,528);
- Satisfaction is highest with oxycodone, alfentanil, remifentanil, fentanyl, and pethidine. Tramadol has the least satisfaction. Other opioids are not different to morphine (17 RCTs, n=1,476).

OIVI is rare with 22 cases reported (n=2,452); sufentanil, alfentanil, remifentanil and morphine have the highest reported rates here.

Two reviews of published RCTs, cohort studies, case-controlled studies and audits reported the following incidences associated with IV PCA use: respiratory depression 1.2 to 11.5% (depending on whether respiratory rate or oxygen saturation were used as indicators), nausea 32%, vomiting 20.7% and pruritus 13.8% (Dolin 2005 **Level IV SR**, 183 studies [PONV] & 89 studies [sedation] & 166 studies [pruritus], n≈100,000; Cashman 2004 **Level IV SR**, 165 studies, n≈20,000). Excessive sedation was not used as an indicator of respiratory depression in any of the studies included in these reviews (see importance of sedation score in Section 4.3.1.4).

The incidence of respiratory depression (<10 breaths/min) with PCA morphine was 0.06% and no patient required naloxone (Cheung 2009 **Level IV**, n=5,137). The incidence of nausea was 47.4% and vomiting was 18.5%; these were most common in female patients and those having gynaecological surgery. The incidence of pruritus was 8%.

In 1.86% of patients who received PCA for postoperative pain relief, respiratory depression (defined as a respiratory rate of <10 breaths/min and/or a sedation score of 2; defined as "asleep but easily roused") was identified; of these 13 patients all had respiratory rates of <10 breaths/min and 11 also had sedation scores of 2 (Shapiro 2005 **Level IV**, n=700).

Impact of adjuvants on IV PCA adverse effects

The combination of NSAIDs with IV PCA morphine reduces adverse effects vs IV PCA morphine alone:

- PONV is reduced by 30% (OR 0.70; 95%CI 0.53 to 0.88) (Maund 2011 **Level I**, 60 RCTs, n unspecified);
- Sedation is reduced by 29%, while respiratory depression, pruritus and urinary retention are not reduced (Marret 2005 **Level I**, 22 RCTs, n=2,307).

These benefits are most likely due to the opioid-sparing effect of concurrent NSAIDs, rather than a direct effect of NSAIDs themselves. Similar beneficial effects have also been found for the addition of IV ketamine via various regimens (Assouline 2016 **Level I** [PRISMA], 19 RCTS, n=1,453; Wang 2016 **Level I** [PRISMA], 36 RCTs, n=2,502) (12 RCTs overlap), gabapentin (Fabritius 2016 **Level I** [PRISMA], 132 RCTs, n=9,498), pregabalin (Fabritius 2017 **Level I** [PRISMA], 97 RCT, n=7,201), IV lidocaine (Weibel 2018 **Level I** [Cochrane], 68 RCTs, n=4,525) and the alpha-2 agonists clonidine (Sanchez Munoz 2017 **Level I** [PRISMA], 57 RCTs, n=14,790) and dexmedetomidine by various administration regimens (Wang 2018 **Level I** [PRISMA], 40 RCTs, n=2,401).

6.3.3 | Adjuvant medicines

Discussion of adjuvant medicines in this section will be confined to those added to the PCA opioid solution. For additional information see Chapter 4.

6.3.3.1 | Antiemetics

Droperidol added to the PCA morphine solution is effective in preventing nausea (NNT 2.7; 95%CI 1.8 to 5.2) and vomiting (NNT 3.1; 95%CI 2.3 to 4.8) with no apparent dose-responsiveness (Tramer 1999 **Level I**, 6 RCTs [droperidol], n=642). Adverse effects were not increased when the dose of droperidol was <4 mg/d. However, in a subsequent comparison of 0.5 mg, 1.5 mg and 5 mg droperidol added to 100 mg PCA morphine, the smallest dose had no significant antiemetic effect and the 1.5 mg dose was effective against nausea (NNT 6.3; 95%CI 3.3 to 100) but not vomiting (Culebras 2003 **Level II**, n=340, JS 4). The 5 mg dose significantly reduced both nausea and vomiting but at the cost of unacceptable sedation (NNH 6.4; 95%CI 4.1 to 15), which was not seen at the other doses. The 1.5 mg and 5 mg doses also reduced pruritus. There was no difference in dysphoric effects. In another RCT, droperidol 5 mg added to morphine 100 mg by PCA resulted in morphine-sparing and, in the first 24 h after surgery, reduced the frequency of PONV (Lo 2005 **Level II**, n=179, JS 5). While, droperidol given as a single dose at the end of surgery was as effective as adding droperidol to PCA morphine (Gan 1995 **Level II**, n=82, JS 3). The cost-benefit and risk-benefit of the routine addition of droperidol to PCA opioids must therefore be considered, because all patients receive the medication when not all will need it and some patients might receive inappropriately high doses of droperidol.

Evidence of benefit from the addition of $5HT_3$ antagonists to IV PCA is unclear. Ondansetron, given both as a bolus at the end of surgery and mixed with morphine in the PCA solution, reduced the incidence of nausea and the need for additional antiemetics but not the patients' perception of their overall satisfaction with care (Cherian 2001 **Level II**, n=81, JS 4). Adding ondansetron to PCA opioids reduces nausea and/or vomiting (NNT 2.9; 95%CI 2.1 to 4.7) (Tramer 1999 **Level I**, 2 RCTs [ondansetron], n=184). A later study showed that ondansetron given as an initial dose of 4 mg followed by 0.2 mg/1 mg morphine PCA morphine could reduce nausea and vomiting; although pain scores were higher (Boonmak 2007 **Level II**, n=160, JS4). The combination of ondansetron plus prochlorperazine to IV PCA morphine was more effective than ondansetron alone (Jellish 2009 **Level II**, n=150, JS 4).

Dexamethasone 8 mg given at the start of surgery reduced the incidence of severe nausea and vomiting only vs ondansetron at the end of surgery in patients receiving PCA fentanyl with added ondansetron (12 mg added to 2 mg fentanyl) (Song 2011 **Level II**, n=130, JS 4). The addition of midazolam to PCA morphine had a similar antiemetic effect to that of ondansetron but was associated with an increase in mild sedation (Huh 2010 **Level II**, n=90, JS 3).

6.3.3.2 | Ketamine

Two systematic reviews evaluated the effect of peri- and postoperative ketamine (sub-anaesthetic doses) coadministered as an adjuvant to PCA (morphine 15 RCTs and 1 RCT each in adults for tramadol & fentanyl and in adolescents for fentanyl & hydromorphone) (Assouline 2016 **Level I** [PRISMA], 19 RCTs, n=1,453) and to PCA morphine (33 RCTs, n=2,374) or PCA hydromorphone (3 RCTs, n= 128) (Wang 2016 **Level I** [PRISMA], 36 RCTs, n=2,502) (12 RCTs overlap).

Adding ketamine to an opioid in the PCA pump in various ratios has benefits to pain scores at rest at 24 h (WMD 21.1/100; 98%CI 21.8 to 20.39) (9 RCTs, n=595) and opioid consumption (-28%) (7 RCTs, n=495) and PONV (-44%) (7 RCTs, n=435) (Assouline 2016 **Level I** [PRISMA], 19 RCTs, n=1,453). Respiratory depression (RR 0.31; 98%CI 0.06 to 1.51) (9 RCTs, n=871) and hallucinations (OR 1.16; 98%CI 0.47 to 2.79) (7 RCTs, n=690) are not increased. A parallel meta-analysis on ketamine added to morphine or hydromorphone PCA confirms these results (Wang 2016 **Level I** [PRISMA], 36 RCTs, n=2,502) (12 RCTs overlap). There was no dose-response effect found and the optimum analgesic/sub-anaesthetic dose is uncertain.

IV ketamine PCA vs hydromorphone PCA reduced supplemental analgesia and need for supplemental oxygenation, but was associated with more hallucinations (Takieddine 2018 **Level II**, n=20, JS 5).

The stability and compatibility of mixtures of tramadol with ketamine in polyolefin bags were satisfactory over a test period of 14 d at 4° and 25°C (Gu 2015 **BS**).

For more details see also Section 4.6.

6.3.3.3 | Naloxone

There was no analgesic benefit of adding naloxone to the PCA morphine solution (Cepeda 2004 **Level II**, n=265, JS 5; Sartain 2003 **Level II**, n=96, JS 5; Cepeda 2002 **Level II**, n=166, JS 5); with "ultra-low doses" only (naloxone 0.6 mcg per morphine 1 mg), the incidence of nausea and pruritus was decreased (Cepeda 2004 **Level II**, n=265, JS 5).

6.3.3.4 | Other adjuvants

Ketorolac added to morphine (Chen 2009 **Level II**, n=102, JS 5; Chen 2005b **Level II**, n=79, JS 5) or tramadol (Lepri 2006 **Level II**, n=60, JS 3) by PCA did not improve pain relief or alter the incidence

of adverse effects; however, it was opioid-sparing and led to an earlier return of bowel function after colorectal surgery (Chen 2009 **Level II**, n=102, JS 5).

The addition of lidocaine to morphine conferred no benefit in terms of pain relief or adverse effects (Cepeda 1996 **Level II**, n=195, JS 5).

The addition of clonidine to IV PCA morphine resulted in significantly better pain relief for the first 12 h only, and less nausea and vomiting vs morphine alone; there was no reduction in morphine requirements (Jeffs 2002 **Level II**, n=60, JS 5).

Dexmedetomidine/morphine by IV PCA resulted in better pain relief (at rest and movement), significant opioid-sparing (29%) and a lower incidence of nausea vs IV PCA morphine alone (Lin 2009 **Level II,** n=100, JS 5). Adverse cardiovascular effects, sedation or respiratory depression were not increased in the dexmedetomidine/morphine group. Dexmedetomidine/sufentanil IV PCA sufentanil IV PCA alone in patients having elective abdominal surgery (laparoscopic and open) improved pain relief at rest and with movement, nausea (25% vs 12.5%) and vomiting (18.2% vs 6.25%) (Gao 2018 **Level II**, n=210, JS 4).

Magnesium added to morphine was opioid-sparing and led to better pain relief (Unlugenc 2003 **Level II**, n=90, JS 3); added to tramadol, it was opioid-sparing but only provided better pain relief for the first 2 h (Unlugenc 2002 **Level II**, n=66, JS 4).

Midazolam/morphine IV PCA after spinal surgery reduced anxiety and provided a small reduction in the pattern of morphine consumption over time vs IV PCA morphine (Day 2014 **Level II,** n=29, JS 4). Sedation scores were not reported.

The addition of nalbuphine to PCA morphine resulted in reduced pruritus without affecting pain relief (Yeh 2008 **Level II**, n=311, JS 5).

6.4 | Program parameters for IV PCA

6.4.1 | Bolus dose

While the optimally sized bolus dose should provide good pain relief with minimal adverse effects, there are only limited data available concerning the effects of various dose sizes. In patients prescribed 0.5 mg, 1 mg and 2 mg bolus doses of morphine, most of those who were prescribed 0.5 mg were unable to achieve adequate analgesia, while a high incidence of respiratory depression was reported in those who received 2 mg (Owen 1989a **Level II**, n=21, JS 3). It was concluded that the optimal PCA bolus dose for morphine was therefore 1 mg.

Similarly, in patients prescribed 20, 40 or 60 mcg bolus doses of fentanyl, the larger dose was associated with an increased risk of respiratory depression and a conclusion was made that the optimal dose of fentanyl for use in PCA was 40 mcg (Camu 1998 **Level II**, n=150, JS 4). However in this study, each dose was infused over 10 min, which could alter the effect of that dose.

Four different demand doses of fentanyl (10, 20, 30 and 40 mcg) were assessed for the management of pain during changes of burns dressings. Pain relief was significantly better with the 30 mcg and 40 mcg doses; no patient became sedated or experienced nausea and vomiting (Prakash 2004 **Level II**, n=60, JS 2).

Rigid adherence to an "optimal" dose may not, however, lead to the best pain relief for all patients. If the prescribed dose is not "optimal" and not too small, the patient will be able to compensate to some degree by changing their demand rate. However, they will only compensate to a certain degree. Even if uncomfortable, patients may only average four demands/h, even though they could press the PCA button more frequently (Owen 1989a **Level II**, n=21, JS 3).

Initial orders for bolus doses should take into account factors such as a history of prior opioid use (see Section 9.7) and patient age (Macintyre 2015 **NR**; Macintyre 2008 **NR**). PCA morphine requirements are known to decrease as patient age increases (Gagliese 2008 **Level IV**, n=246; Macintyre 1996 **Level IV**, n=1,010) (see also Section 9.2.4.2). Subsequent bolus doses may require adjustment according to patient pain reports or the onset of any adverse effects.

The number of demands a patient makes, including the number of "unsuccessful" demands, is often used as an indication that the patient is in pain and as a guide to adjusting the size of the bolus dose. However, there may be a number of reasons for a high demand rate other than pain. For example, excessive PCA demands may correlate with anxiety, poor perioperative adaptation to surgery involving avoidance behaviour and intrusive thoughts, as well as high pain scores (Katz 2008 **Level IV**, n=117). See also Section 1.2.2 for additional information on the relationship between pain relief and psychological factors in PCA.

6.4.2 | Lockout interval

The lockout interval is a safety mechanism that limits the frequency of doses delivered to the patient. For maximum safety, it should be long enough to allow the patient to feel the full effect of one opioid dose before another dose can be delivered. However, if it is too long the effectiveness of PCA could be reduced. There were no differences in pain relief, adverse effects or anxiety when lockout intervals of 7 or 11 min for morphine and 5 or 8 min for fentanyl were used (Ginsberg 1995 **Level II**, n=78, JS 4).

6.4.3 | Concurrent background (continuous) infusions

When a background infusion is used, opioid will continue to be delivered regardless of the patient's sedation level or respiratory status. The addition of a continuous background infusion significantly increases the risk of respiratory depression (OR 4.68; 95%CI 1.20 to 18.21) (George 2010 **Level I** [Cochrane], 14 RCTs, n=769); in 12 of the 14 RCTs, morphine was used. The risk was increased in adults in comparison to children (OR 10.2; 95%CI 3 to 35) (11 adult, 1 mixed, 2 paediatric). The definition of respiratory depression in this meta-analysis was either respiratory rate ≤10, saturation ≤90% or $PaCO_2$ ≥50.

There is no good evidence to show that the addition of a background infusion to IV PCA improves pain relief or sleep or reduces the number of demands (Dal 2003 **Level II**, n=35, JS 3; Parker 1992 **Level II**, n=156, JS 2; Parker 1991 **Level II**, n=230, JS 3; Owen 1989b **Level II**, n=22, JS 2). In adults, the routine use of a background infusion is therefore cautioned against, although it may be useful in opioid-tolerant patients (see Section 9.7).

Limited data found that the use of time-scheduled decremental continuous infusion of opioid added to the PCA program provided better pain relief than bolus only PCA in women having laparoscopic gynaecological surgery (Zhu 2019 **Level II**, n=90, JS 5; Kim 2013 **Level II**, n=99, JS 4). The use of PCA with a variable rate feedback background infusion in patients having spinal fusion surgery showed equivalent analgesia, and less total opioid dose than PCA with a constant rate background infusion (Lee 2019 **Level II**, n=78, JS 5). Estimating the risk of respiratory depression with these techniques from small studies is not possible.

6.4.4 | Dose limits

Limits to the maximum amount of opioid that can be delivered over a certain period (commonly 1 or 4 h) can be programmed into most PCA machines. There is no good evidence of any benefit that can be attributed to these limits (Macintyre 2015 **NR**).

6.4.5 | Loading dose

There is enormous variation in the amount of opioid a patient may need as a "loading dose", and there is no good evidence of any benefit that can be attributed to the use of the loading dose feature that can be programmed into PCA machines. PCA is essentially a maintenance therapy; therefore adequate pain relief should be established before PCA is started by administration of individually titrated loading doses (Macintyre 2015 **NR**; Macintyre 2008 **NR**). IV opioid loading improved the analgesic efficacy of subsequent oral and PCA opioid therapy in the treatment of acute sickle cell pain (Rees 2003 **GL**).

When administering IV loading doses of opioids, lipophilic medicines such as fentanyl are more appropriate than morphine for titrating analgesia because they equilibrate more quickly with the brain. While plasma and CNS fentanyl levels equilibrate within minutes, morphine takes many hours, which can lead to OIVI occurring well after a patient has been deemed "comfortable" and discharged from a high acuity area to a lower level area (eg PACU or ED to the ward) (Aubrun 2012 **NR**; Lötsch 2005 **NR**).

6.5 | Efficacy of PCA using other systemic routes of administration

6.5.1 | Subcutaneous PCA

Data on the effectiveness of SC PCA vs IV PCA are variable and inconsistent. Both similar (Bell 2007 **Level II**, n=130, JS 3; Munro 1998 **Level II**, n=80, JS 3; White 1990 **Level II**, n=24, JS 5; Urquhart 1988 **Level II**, n=30, JS 1) and significantly better (Keita 2003 **Level II**, n=40, JS 3; Dawson 1999 **Level II**, n=100, JS 2) pain relief has been reported, as well as the same (Keita 2003 **Level II**, n=40, JS 3; Dawson 1999 **Level II**, n=100, JS 2; Munro 1998 **Level II**, n=80, JS 3; Urquhart 1988 **Level II**, n=30, JS 1) or higher incidence of nausea and vomiting (White 1990 **Level II**, n=24, JS 5) or pruritus (Bell 2007 **Level II**, n=130, JS 3). SC PCA vs IV PCA may result in higher opioid use (Bell 2007 **Level II**, n=130, JS 3; Dawson 1999 **Level II**, n=100, JS 2; White 1990 **Level II**, n=24, JS 5; Urquhart 1988 **Level II**, n=30, JS 1) or may not (Munro 1998 **Level II**, n=80, JS 3).

6.5.2 | Oral PCA

Oral PCA, using a modified IV PCA system, is as effective as IV PCA (Striebel 1998 **Level II**, n=64, JS 2). An oral PCA device has been developed that uses radiofrequency identification (RFID) technology to allow patients in an oncology ward access (subject to a lockout interval) to a medication-dispensing system at the bedside (Rosati 2007 **Level IV**, n=20).

The use of a computer-controlled oral PCA dispensing device (the PCoA® Acute Device) was compared to conventional nurse-administered on-request oral opioid analgesia in patients having a variety of elective surgical procedures (Wirz 2017 **Level II**, n=70, JS 3). This device allowed secure patient access to bedside oral opioid analgesia (oxycodone or morphine) via RFID technology with higher use of opioid analgesia.

6.5.3 | Sublingual PCA

A sublingual sufentanil tablet system (SSTS) has been trialled in both postsurgical and other acute pain settings. When compared to IV morphine PCA for analgesia after major abdominal or arthroplasty surgeries, SSTS 15 mcg provided analgesia that was noninferior to IV PCA with a similar rate of adverse effects and superior satisfaction ratings from patients and nursing staff (Melson 2014 **Level II**, n=357, JS 2). Specifically for postarthroplasty pain management, SSTS 15 mcg was found to be superior to placebo but with a higher rate of nausea and vomiting (Jove 2015 **Level II**, n=419, JS 5). For abdominal surgeries, the analgesia from SSTS was superior to placebo with similar adverse events profiles for 15 mcg (Ringold 2015 **Level II**, n=172, JS 5) and 30 mcg, with rapid onset of reported analgesic effect within 15 min of administration (Minkowitz 2017 **Level II**, n=161, JS 5). SSTS 30 mcg was also trialled for acute pain management in the ED setting (Miner 2018 **Level III-3**, n=76). See also Section 6.7.2.2 below.

6.5.4 | Intranasal PCA

IN PCA fentanyl can be as effective as IV PCA (Paech 2003 **Level II**, n=24, JS 3; Manjushree 2002 **Level II**, n=40, JS 4; Toussaint 2000 **Level II**, n=57, JS 3; Striebel 1996 **Level II**, n=50, JS 2), as is IN PCA butorphanol (Abboud 1991 **Level II**, n=186, JS 2). As would be expected from the data on IN bioavailability of opioids (see Section 5.5.2), higher doses are needed via the IN route (Manjushree 2002 **Level II**, n=40, JS 4; Striebel 1996 **Level II**, n=50, JS 2). IN PCA pethidine is as effective as IV PCA pethidine, although larger doses are needed (Striebel 1993 **Level II**, n=112, JS 3), and more effective than SC injections of pethidine (Striebel 1995 **Level II**, n=44, JS 2).

Diamorphine IN PCA (bolus doses of 0.5 mg) is less effective than IV PCA morphine (non-equivalent higher bolus doses of 1 mg were used) after joint arthroplasty surgery (Ward 2002 **Level II**, n=52, JS 2). It provided better pain relief in doses of 0.1 mg/kg vs 0.2 mg/kg IM morphine in children with fractures (Kendall 2003 **NR**). See also Section 6.7.2.3 below.

6.5.5 | Transdermal PCA

Iontophoretic TD fentanyl PCA provided analgesia superior to placebo but significantly more patients in the TD group withdrew because of inadequate analgesia vs IV PCA morphine (Poon 2009 **Level I** [QUOROM], 6 RCTs, n=2,866). There was no difference in patient global assessment.

Maximum blood concentrations of fentanyl were the same if the fentanyl patient-controlled TD patch was placed on the chest or upper outer arm, but less if placed on the lower inner arm; the pharmacokinetics were not affected by gender, ethnicity, age or weight (Gupta 2005 **Level IV PK**). See also Section 6.7.2.4 below.

6.6 | Safety and complications related to PCA

Complications related to the use of PCA can be divided into operator or patient-related errors, and problems due to the equipment, practice environment or opioid used.

A large case series of PCA use (by IV, epidural and regional routes) including various device types (elastomeric, CO2 driven, semiprogammable disposable and programmable electronic) reported an incidence of adverse events related to with human error (0.74%), and device-related errors (0.19%) (Son 2019 **Level IV**, n=82,685). Human error in this study included the process of PCA solutions prepared by clinical staff rather than prepared commercially. The highest device error-rates occurred in the programmable electronic device group. Adverse events were associated with 63% of the errors and two patients had severe respiratory depression requiring ICU admission; there was no PCA-related death.

An early prospective study of patients given PCA postoperatively found nine cases of respiratory depression (Looi-Lyons 1996 **Level IV**, n=4,000). These were associated with drug interactions, continuous (background) infusions, nurse- or physician-controlled analgesia, and inappropriate use of PCA by patients. A similar sized prospective study showed that use of PCA was associated with 14 critical events: 8 programming errors (all associated with the setting of a continuous infusion); 3 family members activating PCA; 1 patient tampering; and 3 errors in clinical judgment (Ashburn 1994 **Level IV**, n=3,785).

Analysis of data from the USA FDA's Manufacturer and User Facility Device Experience (MAUDE) database shows that 76.4% of adverse effects related to IV PCA were attributed to technical problems with devices (eg frayed wires or cracks in syringes/ cartridges) and 6.5% were caused by operator error (Schein 2009 **Level** IV, n=2,009 [events]). Of these operator errors (n=131 events), most (81%) related to pump misprogramming and 48% were associated with patient harm. In contrast, only 0.5% of technical device problems resulted in patient harm.

A later retrospective analysis (from July 2000 to June 2005) reported to a national voluntary medication error-reporting database (MEDMARX), showed that PCA-related medication errors continue where 9,571 (1%) were related to PCA use (Hicks 2008 **Level IV**, n= 919,241 [errors]). Of these, 624 (6.5%) were associated with patient harm. By comparison, only 1.5% of medication error reports in general led to harm. The majority of PCA errors occurred during the administration of the medication. Of these, 38% were errors in dose or quantity, 17.4% involved an omission and 17.3% were related to an unauthorised or wrong medicine; human

factors were the main cause of errors; distractions (37.8%) and inexperienced staff (26.3%) were the leading contributing factors. Overall, human factors were the leading cause of PCA errors. A postmarketing surveillance program (2011 to 2016) by the FDA identified 1,430 events with use of IV PCA, of which 11% were associated with an unfavorable clinical outcome; device related issues, which were mostly identified as preventable, occurred in 87% of these (Lawal 2018 **Level IV**, n=1,430 [events]). The authors suggest that education, training and development of improved safety features for PCA devices are needed to improve the overall safety of PCA use.

The implementation of "smart pump" technologies may reduce the incidence and severity of PCA pump programming errors (Ohashi 2014 **Level IV SR** [PRISMA], 22 studies, n unspecified; Mai 2012 **Level III-3**). These technologies include the adoption of standardised and preselected medicine concentrations and dosages. Additionally, the extent of dose sizes is limited to safe ranges through the use of "soft" and "hard" limits.

The safety of PCA can be improved by the use of a hospital-wide safety improvement program (Paul 2010 **Level III-3**, n=25,198). A large prospective survey initially found that the incidence of errors with the use of PCA was 0.25%. Following the introduction of a safety improvement initiative, the incidence of PCA errors was reduced to 0.09% (OR 0.28; 95%CI 0.14 to 0.53).

The costs and rates of errors due to the use of IV PCA were estimated from two large safety-reporting databases in the USA (Meissner 2009 **Level IV**). The datasets included medication errors and device errors. The estimated average cost of a PCA adverse effect in the medication error dataset was US$733, whereas the cost related to a pump error was US$552. An error which lead to patient harm cost 120–250 times more than a non-harmful error. The estimated annual error rates per 10,000 patients in the USA using PCA were 407 for PCA drug errors and 17 for PCA device errors.

The safety of PCA prescribing and patient observation may be improved by the adoption of a common and standardised form and process that incorporates human factors and safety triggers (Agency for Clinical Innovation 2014 **GL**).

PCA safety can be addressed through a variety of strategies including the adoption of new and emerging technologies such as bar-code scanning of prefilled syringes, computer provider order entry (electronic medication management), and feedback using continuous capnography in combination with pulse oximetry (Ocay 2018 **NR**).

For more detail on adverse effects due to the opioid administered, equipment used or operator and patient-related factors, see Sections 6.3, 6.7 and 6.8 respectively.

6.7 | Equipment

Both programmable PCA pumps and disposable PCA devices are available.

6.7.1 | Programmable PCA pumps

These types of pumps allow significant flexibility of use. Adjustments can be made to the dose delivered and lockout intervals, background infusions can be added and accurate assessments can be made of the total dose of medicine delivered. In addition, access to the syringe (or other medicine reservoir) and the microprocessor program is only possible using a key or access code.

All require disposable items eg generic or dedicated syringes or cartridges, antisiphon valves (to prevent siphoning of medicine from the medicine reservoir) and anti-reflux valves (to prevent backflow of medicine into the IV infusion line). See Section 6.7.3 below.

6.7.2 | Disposable PCA devices

6.7.2.1 | Parenteral PCA devices

Disposable PCA devices are often based on the same physical principle; the volume of pressurised fluid delivered (dependent upon spring or elastomer technology) is determined by mechanical restrictions within the flow path and the speed of filling of the bolus dose reservoir determines the lockout interval (Skryabina 2006 **NR**). Advantages include small size and weight, freedom from an external power source, elimination of programming errors and simplicity of use. Disadvantages include an inability to alter the volume of the bolus dose delivered or add a background infusion, difficulties accurately determining the amount of medicine the patient has received, the possibility of inaccurate flow rates, and long-term costs (Skryabina 2006 **NR**). There may also be security issues as the medicine reservoirs for these devices are more readily accessible.

6.7.2.2 | Sublingual PCA devices

A sublingual sufentanil tablet system (SSTS) has been developed commercially and incorporates a hand-held computerised dispenser which is activated by an RFID tag linked to an individual patient, and dispenses SL sufentanil 15 mcg tablets in a patient-controlled manner with a 20 min lockout (Frampton 2016 **NR**).

6.7.2.3 | Intranasal PCA devices

Metered-dose PCINA devices are available. The medicines must be administered in small volumes to avoid significant run-off into the pharynx.

Initial PCINA devices delivered sprays of a reasonable dose but a large volume (eg 25 mcg fentanyl/0.5 mL) (Striebel 1996 **Level II**, n=50, JS 2; Striebel 1993 **Level II**, n=112, JS 3) or smaller volume but with smaller doses than commonly used with IV PCA (eg 9 mcg fentanyl/0.180 mL) (O'Neil 1997 **Level IV**, n=10). A specially formulated solution of 300 mcg/mL fentanyl has been used in a device that enables fentanyl doses of 54 mcg to be delivered in just 0.18 mL (Paech 2003 **Level III-1**, n=21).

6.7.2.4 | Transdermal PCA devices

The iontophoretic TD PCA fentanyl system uses a low-intensity electric current to drive the medicine from the reservoir through the skin and into the systemic circulation (Scott 2016 **NR**). The IONSYS™ device, which is applied to the chest or upper outer arm, delivers a fixed dose of 40 mcg fentanyl over a 10-min period following a patient demand and allows delivery of up to 6 doses/h, up to a maximum of 80 doses in 24 h (Power 2008 **NR**). This device must be replaced every 24 h and is designed for in-hospital use only.

After initial technical difficulties related to corrosion, the device was reapproved by the FDA for short-term use in hospitalised patients in 2015; however, the manufacturer discontinued sale and distribution for business reasons in June 2017 (The Medicines Company 2017).

6.7.3 | Equipment-related complications

In general, modern PCA pumps have a high degree of reliability. However, problems continue to be reported as well as problems related to the disposable items required. Information regarding complications due to equipment problems is mainly case-series or report-based.

While the number of reports of "run-away" pumps, where the PCA pump unexpectedly delivers an unprescribed dose of medication (Notcutt 1990 **Level IV**, n=1,000), has decreased following changes made to pump design, they continue to occur, including a report of spontaneous triggering (Christie 1998 **CR**) and of a frayed wire in the demand apparatus leading to triggering as a result of an electrical short circuit (Doyle 2001 **CR**).

Uncontrolled siphoning of syringe contents when the PCA machine was above patient level has been reported following cracked glass PCA syringes (ECRI 1996 **CR**; Thomas 1988 **CR**), failure of a damaged drive mechanism to retain the syringe plunger (Kwan 1995 **CR**), improperly secured PCA cassettes (ECRI 1995 **CR**) and broken medication cartridge syringe (Doyle 2008 **CR**). To minimise the risk of siphoning, the use of antisiphon valves is recommended (ECRI 1996 **CR**).

Antireflux valves are essential if the PCA infusion is not connected to a dedicated IV line. The non-PCA infusion tubing should have an antireflux (one-way) valve upstream from the connection with the PCA line to prevent back-flow up the non-PCA line should distal obstruction occur; otherwise, inappropriate dosing can occur (Rutherford 2004 **CR**; Paterson 1998 **CR**)

In response to concern about problems with infusion pumps, including PCA pumps, in 2010 the FDA commenced the Infusion Pump Improvement Initiative. Areas for improvement included software, design of user interface, and mechanical and electrical defects (FDA 2010 **GL**). Device-related errors occurred in 0.19% of patients in a large series (Son 2019 **Level IV**, n=82,685). The highest device error-rates occurred in the programmable electronic device group. See also Section 6.6 above.

6.8 | Patient and staff factors

6.8.1 | Patient factors

Patient factors play a role in the effectiveness of PCA as well as complications that can arise from its use; as for equipment issues, much of the information regarding complications due to patient factors is case-based. Psychological factors that may affect PCA use and efficacy are discussed in Section 1.2.2.

6.8.1.1 | Education

Few controlled studies have evaluated the influence of information provision on PCA use. Of patients surveyed who used PCA, approximately 20% were worried that they may become addicted, 20% felt that the machine could give them too much medicine and 30% that they could self-administer too much opioid (Chumbley 1998 **Level IV**, n=200). In a follow-up study, the same group conducted focus groups with previous PCA users, developed a new information leaflet and then undertook a randomised study comparing the old and new leaflet. They found that patients wanted more information on the medication in the PCA, the possible adverse effects and assurance that they would not become addicted (Chumbley 2002 **Level IV**, n=100).

Comparisons have been made between different forms of education given to patients about PCA and results are inconsistent. In an assessment of patient information delivered using structured preoperative interviews or leaflets vs routine preoperative education, patients given leaflets were better informed and less confused about PCA and became familiar with using PCA more quickly but there were no effects on pain relief, worries about addiction and safety or knowledge of adverse effects; the structured preoperative interview resulted in no benefits (Chumbley 2004 **Level III-2**, n=225). Another comparison of structured education vs routine information showed that overall analgesic efficacy, adverse effects and recovery times were not affected by the education program (Lam 2001 **Level II**, n=60, JS 2). Patients who were shown a video on PCA prior to surgery had better knowledge about the technique and reported better pain control after surgery (Chen 2005a **Level III-2**, n=60; Knoerl 1999 **Level III-2**).

6.8.1.2 | Inappropriate use of PCA

The safety of PCA depends on an adequate understanding of the technique by the patient and the fact that unauthorised persons do not press the demand button.

Oversedation with PCA has followed the patient mistaking the PCA handset for the nurse-call button, and family or unauthorised nurse-activated demands ("*PCA by proxy*") (Tsui 1997 **Level IV**, n=2,509; Sidebotham 1997 **Level IV**, n=6,035; Ashburn 1994 **Level IV**, n=3,785; Fleming 1992 **Level IV**, n=1,122; Chisakuta 1993 **CR**; Wakerlin 1990 **CR**).

There have been case reports expressing concerns that patients can use PCA to treat increasing pain and therefore mask problems such as compartment syndrome (Richards 2004 **Level IV**, n=4; Harrington 2000 **CR**), urinary retention (Hodsman 1988 **CR**), pulmonary embolism (Meyer 1992 **CR**) and myocardial infarction (Finger 1995 **CR**). However, appropriate routine patient monitoring should detect changes in pain scores and analgesic consumption enabling identification of such complications.

6.8.2 | Nursing and medical staff

The information regarding complications due to nursing and medical staff factors is also case-based.

Of 9,571 PCA-related adverse effects, 69.8% were related to human factors (Schein 2009 **Level IV**). Improper dose and quantity was the most common factor in 38.9%.

As noted above, operator error is a common safety problem related to PCA use (Looi-Lyons 1996 **Level IV**, n=4,000; Ashburn 1994 **Level IV**, n=3,785). Misprogramming of PCA pumps is thought to account for around 30% of PCA errors, be twice as likely to result in injury or death than errors involving general-purpose infusion pumps and lead to more harm than errors in other types of medication administration (ECRI 2006 **NR**). Mortality from programming errors has been estimated to range from 1 in 33,000 to 1 in 338,800 patients prescribed PCA (Vicente 2003 **NR**).

A number of reports involve the programming of medication concentrations that were lower than the concentration used, with the resultant delivery of an excessive amount of opioid leading to respiratory depression and sometimes death (ECRI 2002 **Level IV**; ECRI 1997 **Level IV**). The use of an incorrect prefilled "standard syringe" for PCA (morphine 5 mg/mL instead of the prescribed 1 mg/mL) also had a fatal outcome (Vicente 2003 **CR**). It has been suggested that medicine concentrations should be standardised within institutions to reduce the chance of administration and programming errors (ECRI 2002 **Level IV**).

PCA pumps using "smart pump" technology now incorporate dose error reduction systems described in Section 6.2 above.

Inappropriate prescriptions of supplementary opioids (by other routes) and sedative medicines (including some antihistamines) can lead to oversedation and respiratory depression (Tsui 1997 **Level IV**, n=2,509; Ashburn 1994 **Level IV**, n=3,785; Lotsch 2002 **NR**).

Human error occurred in 0.74% of patients in a large series, including mistakes with the preparation of PCA solutions by clinical staff rather than prepared commercially (Son 2019 **Level IV**, n=82,685). Documentation of the management of patient care during PCA use can be significantly improved with the PCA smart pump transmitting data directly into the electronic medical record. This automated integration resulted in an increased rate of fully completed PCA charts from 38% to 91% (Suess 2019 **Level III-3**, n=113).

6.9 | PCA in specific patient groups

For PCA use in the paediatric patient see Section 10.5.2, the obstetric patient Section 9.1.3.1,, the elderly patient Section 9.2, the patient with sleep disordered breathing Section 9.4, and the opioid-tolerant patient Section 9.7 respectively.

KEY MESSAGES

1. Intravenous opioid PCA provides better analgesia than conventional parenteral opioid regimens (**S**) (**Level I** [Cochrane Review]).
2. Opioid administration by IV PCA leads to higher opioid consumption, a higher incidence of pruritus, but no difference in other opioid-related adverse effects, or hospital stay compared with traditional methods of intermittent parenteral opioid administration (**S**) (**Level I** [Cochrane Review]).
3. Patient satisfaction with intravenous PCA is higher when compared with conventional regimens (**S**) (**Level I** [Cochrane Review]).
4. The adjuvant use of ketamine with PCA opioid (in varying ratios) improves pain relief and reduces opioid consumption along with nausea and vomiting, with no increase in neurocognitive effects including hallucinations (**N**) (**Level I** [PRISMA]).
5. Iontophoretic transdermal fentanyl PCA is not as effective as intravenous morphine PCA, with more patients withdrawing from studies because of inadequate pain relief (**U**) (**Level I** [QUOROM]).
6. In settings where there are high nurse to patient ratios, there may be no difference in the effectiveness of PCA and conventional parenteral opioid regimens (**U**) (**Level I**).
7. Tramadol via intravenous PCA provides effective analgesia comparable to morphine by intravenous PCA (**U**) (**Level I**).
8. The addition of a background infusion to intravenous PCA morphine in adults increases the incidence of respiratory depression (**U**) (**Level I**) and does not improve pain relief or sleep, or reduce the number of PCA demands (**U**) (**Level II**).
9. Different opioids by intravenous PCA show different rates of adverse effects; fentanyl PCA has the least rates of sedation, nausea and vomiting while pruritus is most frequent with morphine PCA (**N**) (**Level I** [NMA]). Furthermore, on an individual patient basis, one opioid may be better tolerated than another (**U**) (**Level II**).
10. There is no analgesic benefit in adding naloxone to the PCA morphine solution; however, the incidence of nausea and pruritus may be decreased (**U**) (**Level II**).
11. Subcutaneous PCA opioids can be as effective as intravenous PCA (**U**) (**Level II**).
12. Intranasal PCA opioids can be as effective as intravenous PCA (**U**) (**Level II**).
13. In the emergency department, PCA morphine compared with IV morphine administered by nursing staff, provides more effective analgesia with more rapid onset and with higher patient satisfaction (**U**) (**Level II**).
14. The safety of PCA use can be significantly improved by hospital-wide safety initiatives (equipment, guidelines, education, monitoring) (**U**) (**Level III-3**).
15. The adoption of “smart pump” technologies in PCA design can improve documentation of patient care (**N**) (**Level III-3**), reduce programming errors and improve safety (**N**) (**Level IV SR**).
16. Operator-error, in particular programming error, remains a common safety problem with PCA useoften leading to patient harm (**S**) (**Level IV**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

- ☑ There is insufficient data to compare the risk of rare but serious adverse events with PCA opioid use to conventionally administered opioid analgesia (**N**).
- ☑ Adequate analgesia needs to be attained prior to commencement of PCA. Initial orders for bolus doses should consider individual patient factors such as a history of prior opioid use and patient age. Individual PCA prescriptions may need to be adjusted (**U**).
- ☑ The routine addition of antiemetics to PCA opioids is not encouraged, as it is of no benefit compared with selective administration (**U**).
- ☑ PCA infusion systems must incorporate anti-siphon valves and, in non-dedicated lines, antireflux valves (**U**).
- ☑ Drug concentrations, prescription and observation forms should be standardised to improve patient safety (**U**).
- ☑ The pharmacokinetics of morphine (long equilibration half-time and active metabolites) may make it less suitable for PCA use than other opioids (**U**).
- ☑ Pethidine, when used in PCA, may cause central nervous system toxicity due to the accumulation of norpethidine (**U**).
- ☑ Improved methods of patient monitoring (eg continuous pulse oximetry, continuous capnography) may offer opportunities to improve safety in at-risk patient groups (**N**).

7.0 | Nonpharmacological techniques

7.1 | Psychological interventions

The role of psychological interventions in the management of acute pain is usually as adjunctive therapies to traditional pharmacological and physical treatment modalities; there is increasing evidence for their role in pre-emptive and multimodal acute pain therapy as well as in reducing the risk of chronic postsurgical pain (CPSP) (Horn 2020 **NR**).

By their very nature, psychological interventions share several common features. Some of these features may also apply to effective pharmacological and physical interventions. Typically, the treatment provider is encouraged to firstly establish a degree of rapport or acceptance with the patient as well as give some information about the purpose and nature of the intervention and reasonable expectations the patient should hold for their outcome. These aspects may be seen as necessary to gain both the informed consent of the patient for treatment, as well as their active cooperation.

Psychological interventions may be divided into four broad categories:

- Information provision (procedural information, description of expected sensory experience or behavioural instructions) (see also Section 3.1.1);
- Stress or tension reduction (relaxation and hypnotic strategies);
- Attentional strategies;
- Cognitive-behavioural interventions.

It should be emphasised that these are rarely 'stand-alone' interventions and elements of each may form a single intervention package.

Similar to physical therapies, a lack of clinician blinding and questions as to what constitutes an adequate psychology placebo arm in an RCT, as well as heterogeneous interventions, limit the strength of conclusions (Guidi 2018 **NR**). In the Cochrane meta-analysis presented below, almost all RCTs were ranked at high risk of performance bias due to lack of clinician blinding (Powell 2016 **Level I** [Cochrane], 105 RCTs, n=10,302).

When pooled for all pre-procedural psychological interventions in a range of surgery types (including cardiothoracic 10 RCTs and coronary artery bypass surgery [CABG] 17 RCTs) and procedures, there is a small reduction in postoperative pain scores (SMD -0.2; 95%CI -0.35 to -0.06) (38 RCTs, n=2,713), length of stay (LOS) (MD -0.52 d; 95%CI -0.82 to -0.22) (36 RCTs, n=3,313) and reduction in negative affect (SMD -0.35; 95%CI -0.54 to -0.16) (31 RCTs, n=2,496) (Powell 2016 **Level I** [Cochrane], 105 RCTs, n=10,302). However, multiple pooled psychological interventions for acute pain after open heart surgery do not reduce postoperative pain intensity or PCA usage but do slightly reduce postoperative mental distress over the short and longer term in RCTs of low quality (Ziehm 2017 **Level I** [Cochrane], 23 RCTs, n=2,669) (5 RCTs overlap).

For paediatric specific information, see Sections 10.7.5 and 10.11.1.

7.1.1 | Provision of information

7.1.1.1 | Procedural information

Procedural information is information given to a patient before any treatment that summarises what will happen during that treatment. Here, four information factors were each associated with global evaluations of care by patients: surgical information, recovery information, general

information and sensory information (Krupat 2000 **Level IV**, n=3,602). Procedural information (often combined with behavioural instructions, like exercises or body positions) effectively reduces reported pain in 3 of 7 RCTs and pain medications in 7 of 12 RCTs (Johnston 1993 **Level I**, 38 RCTs, n=1,734).

In orthopaedic surgery, patient education regarding the procedure or recovery provided a small improvement in post-operative pain (SMD -0.21; 95%CI -0.02 to -0.39) (12 RCTs, n=1,242), pre-operative anxiety (SMD -0.27; 95%CI -0.10 to -0.44) (12 RCTs, n=1,260) and post-operative anxiety (SMD -0.26; 95%CI -0.08 to -0.43) (11 RCTs, n=921), but had no impact on analgesic use (10 RCTs, n=860) (Szeverenyi 2018 L**evel I** [PRISMA], 62 RCTs, n=4,908).

7.1.1.2 | Sensory information

Sensory information is information that describes the sensory experiences the patient may expect during treatment. Sensory information given alone has some positive, albeit inconsistent, effects vs no instruction (Suls 1989 **Level III-3 SR**, 21 studies, n unspecified). With all but two studies involving adults, sensory information reduced self-rated pain more than procedural information; however, the effect sizes were variable. In contrast, a subsequent meta-analysis shows a beneficial effect on pain in three RCTs and shows a reduction in the use of pain medication in two of five RCTs (Johnston 1993 **Level I**, 38 RCTs [7 RCTs sensory information], n=1,734). A subsequent RCT found sensory only information had no significant effect on postoperative pain perception (Campbell 1999 **Level II**, n=63, JS 2).

7.1.1.3 | Combined sensory-procedural preparatory information

Combined sensory-procedural preparatory information, when compared to procedural information and sensory information given alone, yielded the strongest and most consistent benefits in reducing negative affect, pain reports and other related distress (Suls 1989 **Level III-3 SR**, 21 studies, n unspecified). However, many studies relate to medical procedures such as pelvic examination or to experimental pain. Subsequent systematic reviews are consistent with these findings (Johnston 1993 **Level I**, 38 RCTs, n=1,734; Devine 1992 **Level IV SR**, 191 studies, n unspecified). Interventions investigated include the provision of information about medical procedures and associated emotional responses and sensations before, during and after surgery, and instructions about how to adhere to medical advice to support the recovery, with teaching or instructing patients in different relaxation techniques or helping patients to understand their thoughts and feelings that influence their behaviour.

In some patients, especially those with an avoidant coping style, giving too much information or asking them to make too many decisions may exacerbate anxiety and pain (Wilson 1981 **Level II**, n=70, JS 2). However, later evidence suggested that this may not be a strong effect (Miro 1999 **Level II**, n=92, JS 3). Nevertheless, it may be useful to assess a patient's normal approach to managing stress to identify the best option for that patient. This concept is supported by the finding in patients undergoing colposcopy where stress related to the procedure was reduced when information was tailored to individual coping styles (Kola 2013 **Level II**, n=117, JS 2).

See also Section 3.1.1 on patient education.

7.1.2 | Relaxation techniques

Relaxation training usually involves teaching a patient ways to reduce their feelings of stress and/or arousal. Techniques used may be taught by audio recording or written or spoken instructions. The use of audio recording often includes the use of calming music or suitable

imagery (mental pictures of relaxing scenes). Typically, all methods require the patient to practise the technique regularly, especially when feeling stressed. Some methods focus on altering muscle tension, often sequentially, while others focus on altering breathing patterns (eg emphasising releasing tension with exhalation). Relaxation techniques are closely related to, and often indistinguishable from, forms of meditation and self-hypnosis.

A systematic review of relaxation techniques, when used alone for the management of pain after surgery and during procedures, concluded that there was weak evidence to support the use of relaxation in these settings; three of the 7 RCTs reported significant reductions in pain and distress (Seers 1998 **Level I**, 7 RCTs, n=362). Methodological shortcomings of the included RCTs meant that a meta-analysis was not possible, limiting the strength of the findings. Similar conclusions were made in another systematic review, which found that 8 of 15 RCTs (again, most had weaknesses in methodology) demonstrated reductions in pain (Kwekkeboom 2006 **Level I**, 15 RCTs, n=1,269); the most supported methods were progressive muscle relaxation for arthritis pain and a systematic relaxation technique for postoperative pain. Little evidence was found for autogenic training (another relaxation technique), and no support for rhythmic breathing or other relaxation techniques. Another review of studies using relaxation techniques for burns pain also found insufficient high-quality evidence to draw any conclusions but did recommend further research into the use of a technique that combined focusing on breathing and jaw muscle relaxation (de Jong 2006, **Level III-3 SR**, 11 studies, n=1,541) (1 RCT overlap). The most recent meta-analysis found a reduction in post-operative pain (SMD -0.45; 95%CI -0.11 to -0.79) (9 RCTs, n=473) but no effect on analgesic consumption (SMD -0.36; 95%CI 0.25 to -0.98) (7 RCTs, n=183) (Szeverenyi 2018 **Level I** [PRISMA], 62 RCTs, n=4,908) (0 to 1 RCT overlap).

In patients with acute whiplash associated disorder, physiotherapy directed exercises and education combined with stress inoculation training (comprising relaxation training, guidance on problem solving strategies, and their application to stressful situations) reduced pain-related disability vs exercise alone at 6 wk, 6 mth and 12 mth (Sterling 2019 **Level II**, n=108, JS 3).

Studies of relaxation techniques with cancer patients (in acute pain) provide moderately strong support for its effectiveness in improving pain, but also nausea, pulse rate and blood pressure, as well as emotional adjustment variables (depression, anxiety and hostility) (Luebbert 2001 **Level I**, 15 RCTs, n=742).

7.1.3 | Mindfulness-based interventions (MBI)

Mindfulness meditation is a type of attentional technique that includes attending to pain sensations. It has much in common with breathing-based relaxation techniques. This approach encourages the patient to deliberately experience their pain in a calm manner just like any nonpainful sensation (ie without judging it as good or bad), often while engaging in slowed breathing styles (Kabat-Zinn 2003 **NR**). This approach derives from ancient Buddhist methods. Mindfulness-based approaches have been used to promote adjustment in people experiencing chronic pain, often in conjunction with a form of cognitive-behavioural therapy (CBT) called acceptance and commitment therapy (ACT) (McCracken 2007 **Level IV**, n=105).

MBI/ACT for experimental pain vs other emotion-regulation techniques are superior for pain tolerance (except for distraction) but not for pain intensity (Kohl 2012 **Level I EH** [PRISMA], 30 RCTs, n=2,085). Two subsequent RCTs have provided slightly conflicting findings. In healthy participants undergoing experimental pain (electric shock), both acceptance methods and suppression were equally effective, and both were superior to a control condition in reducing pain and anxiety (Braams 2012 **Level II EH**, n=123, JS 3). In contrast, in healthy students,

mindfulness was as ineffective as relaxation training in reducing experimental pain (with the cold-pressor test) (Sharpe 2013 **Level II EH**, n=140, JS 1).

Brief MBI in mostly healthy volunteers (including adult, some children & adolescent groups) or patients with chronic pain delivered by either audio/video recorder instruction or provider delivered instruction is of unclear effectiveness (McClintock 2019 **Level IV SR**, 18 RCTs & 2 studies, n=1,740). However, brief MBI delivered by a clinician and lasting more than 5 min may be more useful than shorter durations and virtual delivery. The single clinical RCT in acute pain included in this review compared brief MBI vs hypnotic suggestions vs psychosocial education in patients with pre-existing "*intolerable pain*" or "*inadequate pain control*" and found both brief MBI and suggestion were superior to education for pain relief, anxiety and desire for opioids (Garland 2017 **Level II**, n=244, JS 3).

A pilot RCT in veterans after major orthopaedic surgery at high risk of CPSP (severe preoperative pain, moderate postoperative pain, depression or anxiety), found a 1 d ACT workshop vs standard care did not reduce time to cessation of pain (HR 1.42; 95%CI 0.68 to 2.95) or cessation of opioids (HR 1.62; 95% CI 0.82 to 3.21) (Dindo 2018, **Level II**, n=88, JS 3).

7.1.4 | Hypnosis

Hypnosis shares many features of relaxation with imagery and has a long history of use in acute pain conditions. Techniques vary but they have the common feature of one person responding to suggestions made by another regarding experiences involving changes in perception, memory and voluntary actions (Kihlstrom 1985 **NR**). The variable nature of hypnotic procedures has made it difficult to compare studies or draw general conclusions (Ellis 1994 **NR**) although some more standardised (according to a manual) procedures have been reported (Liossi 2003 **Level II**, n=80, JS 2).

Preoperative hypnosis was investigated as one of several methods to reduce postoperative pain in surgical patients; there is no effect on postoperative pain but partial support for improvements in psychological wellbeing measures (Nelson 2013 **Level III-1 SR**, 4 studies [hypnosis], n=144). Another meta-analysis looking at women having breast cancer surgery found preoperative hypnosis does not reduce postoperative pain but reduces perioperative distress (Holger 2012 **Level I**, 4 RCTs, n=550). However, a subsequent meta-analysis found that live and recorded hypnosis both reduce anxiety and live hypnosis reduces pain scores (SMD -0.51; 95%CI -0.06 to -0.96) (8 RCTs, n=669) but both have no effect on analgesic use; while therapeutic suggestion has no effect on anxiety, pain scores or analgesic use (Kekecs 2014 **Level I**, 26 RCTs, n=1,890) (2 RCTs overlap).

Note: reversal of conclusion
This reverses the Level I key message in the previous edition of this document; a preceding meta-analysis had described no effect of hypnosis on postoperative pain scores.

For labour, hypnosis (eight antenatal and one intrapartum intervention) may reduce pharmacological analgesic use (RR 0.73; 95% CI 0.57 to 0.94) (8 RCTs, n=2,916) but has no effect on rate of spontaneous vaginal birth (6 RCTs, n=2,361), sense of coping with labour (1 RCT, n=420) or satisfaction with pain relief when combined with either pethidine (1 RCT, n=72) or epidural analgesia (1 RCT, n=127) (Madden 2016 **Level I** [Cochrane], 9 RCTs, n=2,954).

Note: reversal of conclusion
This reverses the Level I key message in the previous edition of this document; a preceding meta-analysis had described no effect of hypnosis in the management of labour pain.

A reduction is seen with hypnosis in a small majority of study measurements during procedural pain in paediatric and adult patients vs standard care, attention control or other active treatments (Kendrick 2016 **Level I** [PRISMA], 29 RCTs, n=2,202).

Hypnosis vs control for needle-related procedural pain in children reduces pain scores (SMD -1.4; 95%CI -2.32 to -0.48) (5 RCTs n=176), distress scores (SMD -2.53; 95%CI -3.93 to -1.12) (5 RCTs, n=176) and behavioural measures of distress (SMD -1.15; 95%CI -1.76 to -0.53) (6 RCTs, n=193) (Birnie 2018 **Level I** [Cochrane], 59 RCTs, n=5,550) (6 RCT overlap). Analgesic benefits of hypnosis are confirmed in children undergoing cancer-related procedures (Tome-Pires 2012 **Level I**, 10 RCTs [procedural pain], n=394) (5 RCTs overlap). See also Section 10.7.5.

7.1.5 | Attentional techniques

A range of attention-based strategies have been reported, from those involving distraction from the pain through shifting attention to cognitive tasks, imagined stimuli or external stimuli (such as audio, video, tactile sensations, smells or a combination) (Bascour-Sandoval 2019 **NR**). Use of distraction (video, toys, music or stories) is effective in infants, young children and adolescents across a range of procedures eg needle-related pain (Birnie 2018 **Level I** [Cochrane], 59 RCTs, n=5,550; Birnie 2015 **Level III-1 SR**, 22 studies, n=1,717 [10 RCTs overlap]; Pillai Riddell 2015 **Level III-1 SR**, 10 studies, n=1,259 [0 RCT overlap]). See also paediatric sections for vaccine injection (10.7.3.4) and other procedural pain (10.7.5) including that related to paediatric cancer (10.8.2) and burns (10.9.2).

Some techniques also involve deliberately attending to the pain (or pain site) but in ways intended to modify the threat value of pain rather than to divert attention from pain. There is some evidence that this method can alter pain perception but possibly mainly among subgroups of patients (Haythornthwaite 2001 **Level II**, n=42, JS 1; Logan 1995 **Level III-2**; Baron 1993 **NR**).

Attempting to alter the patient's emotional state, from distress or fear to relative comfort or peace, is also a common feature of many of these techniques. Commonly, these techniques are used in conjunction with relaxation methods and at times may be inseparable (Williams 1996 **NR**).

Patients may exhibit pre-existing attention bias which prioritises painful sensations or pain-related experiences over other sensory experiences which may be amenable to attention bias modification); however, results are equivocal, especially when used in isolation (Van Ryckeghem 2019 **Level IV SR EH**, 52 studies, n=4,466).

7.1.5.1 | Music

Music therapy may be either active or passive: active therapy is when the patient participates in creating sounds; in passive music therapy, the patient listens to recorded or live music. When played by medical staff or with music therapists, music reduces acute or procedural pain (MD -1.11/10; 95%CI -1.45 to -0.77) (67 RCTs, n=5,679) with other beneficial effects in terms of emotional distress, anaesthetic use, opioid use, non-opioid use, heart rate, blood pressure and respiratory rate (Lee 2016 **Level I**, 97 RCTs, n=9,184). Patient, rather than clinician or researcher selected music, may be most effective (Lunde 2019 **NR**). In two subsequent RCTs, patient selected music was of benefit during shockwave lithotripsy (Cakmak 2017 **Level II**, n=200, JS 3), but Mozart's Symphony No. 40 played during colposcopy provided no benefit (Hilal 2018, **Level II**, n=215, JS 3).

Similarly, music reduces pain in cancer patients (SMD -0.59; 95%CI -0.92 to -0.27) (Bradt 2011 **Level I** [Cochrane], 30 RCTs, n=1,891). In burns patients, music interventions are helpful for pain alleviation, anxiety relief and heart rate reduction (Li 2017c **Level I** [PRISMA], 17 RCTs, n=804).

In children, music is effective during dental procedures (see 10.7.2.7), heel lance (see 10.7.1.1), burns dressing changes (see 10.7.2.9), vaccination (see 10.7.5) and general procedural pain (see 10.7.3.4).

7.1.5.2 | Virtual reality

Virtual reality (VR) has led to reductions in pain unpleasantness and pain-related brain activity in volunteers using thermal pain stimulation and measuring pain-related brain activity with functional magnetic resonance imaging (fMRI): where both opioids and immersive VR reduced pain and the combination was more effective than opioid alone (Honzel 2019 **NR)**.

VR may be effective at reducing procedural pain eg for needles and burns dressing changes vs usual care (SMD -0.49; 95%CI -0.83 to -0.41) (Chan 2018 **Level III-2 SR** [PRISMA], 9 RCTs & 7 crossover studies, n=656). However, studies were heterogeneous and inherently unblinded.

In burns patients, VR reduces pain intensity, time spent thinking about pain and unpleasantness (Luo 2019b **Level I** [PRISMA], 13 RCTs, n=362; Scheffler 2018 **Level I** [PRISMA], 21 RCTs, n=660) (4 RCTs overlap).

See 8.5.5 for more information on VR use in burns pain and 10.7.5 on VR use in the paediatric population.

7.1.5.3 | Smell

Olfaction can induce analgesia and emotional changes in both humans and animals and may play a role in pain therapy (Lotsch 2016 **NR**).

See Sections 4.14.3 and 8.5.5 for effects of aromatherapy in adults and 10.11.1 in paediatric patients.

7.1.5.4 | Tactile sensations

See 10.7.3.4 for information on use of vibration in paediatric vaccine injection pain.

7.1.6 | Cognitive-behavioural interventions

Typically, cognitive-behavioural interventions involve the application of a range of behaviour-change principles, such as differential positive reinforcement of desired behaviours, identification and modification of unhelpful thoughts and goal setting, in order to achieve change in targeted behaviours. In the context of acute pain this would include encouraging the use of the techniques outlined above to modify the pain experience, reduce distress, and to provide alternative, more helpful responses.

Cognitive-behavioural methods focus on both overt behaviours and cognitions (thought processes) in patients, but interactions with environmental factors are also often addressed. This means that interactions between patients and others, especially medical and nursing staff as well as families, may need to be addressed to support the desired responses in the patient. The latter may entail displaying a calm and reassuring manner and encouragement to persevere with a given task or procedure. Specific training in skills (eg relaxation and other coping strategies), other behavioural techniques (eg modelling and systematic desensitisation), information provision and reconceptualisation of the experiences of the patient may also be provided as part of this approach (as outlined above).

Cognitive-behavioural interventions are usually aimed at reducing the distressing or threat value of pain and enhancing a patient's sense of his or her ability to cope with pain (pain self-efficacy). Effective coping with pain may be reflected in minimal pain-related distress (eg reduced catastrophising) or disability (interference in normal activities). If patients are able to perceive their pain as less threatening, they might also evaluate their pain as less severe. However, in this context, reduced severity would be seen more as a by-product than as the primary goal.

Critically, in using cognitive-behavioural methods, the patient must be an active participant in the process, rather than a passive recipient, as he or she must apply the methods taught as needed.

7.1.6.1 | Applying pain coping strategies within a cognitive-behavioural intervention

Generally, while some responses by patients to their pain may be helpful, others may not. For example, those who respond with overly alarmist (or catastrophic) thoughts tend to experience more pain and distress, vs those who do not respond in this way (eg Haythornthwaite 2001 **Level II**, n=42, JS 1; Sullivan 2001 **NR;** Jensen 1991 **NR**). Identifying unhelpful responses, whether they are cognitive or behavioural, and changing these responses is a common feature of many cognitive-behavioural interventions.

Catastrophic thinking has been associated with increased postsurgical acute pain, opioid use and reduced function (Darnall 2016 **NR**) as well as being a risk factor for development of persistent postsurgical pain (OR 1.55-2.10) (15 RCTs) (Theunissen 2012 **Level IV SR**, 29 studies, n=6,628). Thus, identifying and reducing catastrophic thoughts about pain has become a common intervention within this approach, whether the pain is acute or persistent. A single preoperative 130 min lecture session was effective at reducing pain catastrophisation (Darnall 2014 **Level III-2**, n=76). Before breast cancer surgery, delivery of virtual psychoeducation vs general health education reduced time to opioid cessation (5 d vs 13) (Darnall 2019 **Level II**, n=68, JS 3). However, attrition rates were higher in the psychoeducation group vs general education (44% vs 18%). For breast cancer surgery, patients who received stress management training (mainly relaxation and coping skills) had less depression and fatigue up to 3 mth post-surgery, but there were no differences for anxiety, pain and sleep problems vs a usual care control group (Garssen 2013 **Level II**, n=70, JS 3).

Perioperative CBT may improve pain and functional outcomes; however, heterogeneity of interventions (only in 1 of 6 RCTs delivered by psychologist), outcome measures and time frames limits firm conclusions (Nicholls 2018 **Level I** [PRISMA], 6 RCTs, n=578). A previous meta-analysis found that during preparation for surgery or painful medical procedures, training in cognitive coping methods and behavioural instructions in addition to relaxation training and procedural information, improves patients' pain measures and reduces postoperative use of analgesics (Johnston 1993 **Level I**, 38 RCTs, n=1,734). These interventions effectively improve measures of negative affect, LOS, and recovery.

It has also been recognised that a given coping strategy may not always be useful and that this may depend upon circumstances and timing (Turk 2002 **NR**). For example, ignoring or denying the presence of pain may be useful when first injured (to reduce distress) but, if it means that appropriate help is not sought, it could place the person in danger or at risk of treatment for complications being delayed.

Details on the psychological management of post-operative pain have been incorporated into guidelines (Chou 2016 **GL**).

For information on paediatric cognitive behavioural interventions for procedural pain see 10.7.5.

7.1.6.2 | Complex psychosocial interventions

Increasingly, researchers are reporting the application of psychologically-based interventions in complex acute pain settings, especially in relation to work-related injuries and their management. Instead of employing a single technique (like relaxation), the researchers may employ strategies aimed at the patient's responses (eg distress and avoidance) as well as the responses of key environmental factors, such as in the workplace and in the family.

Injured workers identified within 5 to 15 d of injury as at risk for delayed recovery offered a comprehensive management plan (that included medical/physical treatments, brief CBT-based intervention by a psychologist, and workplace accommodations) had half the time off work (32 d vs 67 d) in the following 2 y vs the usual care recipients (Nicholas 2020 **Level III-2**, n=113). These results are consistent with those reported by a systematic review of interventions for return to work (Cullen 2018 **Level III-2 SR,** 36 studies**,** n≈195,722).

KEY MESSAGES

1. Preoperative psychological interventions may be effective at reducing pain, length of stay and negative affect after various procedures (**N**) (**Level I** [Cochrane Review]) but may not be effective after cardiac surgery (**N**) (**Level I** [Cochrane Review]).
2. Distraction (including with video, toys, music or stories) and hypnosis reduces needle related pain (**S**) and distress (**N**) in children and adolescents (**Level I** [Cochrane Review])
3. Hypnosis may reduce procedural pain and anxiety (**N**) (**Level I** [Cochrane Review]), postoperative pain (**R**) (**Level I**), postoperative anxiety (**N**) and analgesia consumption in labour (**R**) (**Level I** [Cochrane Review]).
4. Listening to music produces a small reduction in postoperative or procedural pain, analgesic requirements and emotional distress (**S**) (**Level I**); patient selected music may be more effective than clinician selected music (**N**) (**Level II**).
5. Patient education regarding the procedure or recovery may reduce postoperative pain (**Q**), preoperative anxiety (**N**) and postoperative anxiety (**N**) but does not affect analgesia use (**U**) (**Level I** [PRISMA]).
6. Training in coping methods or behavioural instruction prior to surgery reduces pain, negative affect and analgesic use (**U**) (**Level I**).
7. Relaxation techniques may reduce postoperative pain but do not reduce analgesic consumption (**S**) (**Level I**).
8. Immersive virtual reality distraction is effective in reducing pain (**S**) and anxiety (**N**) in some clinical situations (**Level III-2 SR** [PRISMA]).
9. In work injury-related acute pain, psychologically informed and workplace-oriented interventions may reduce time lost from work (**N**) (**Level III-2 SR**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Pain catastrophisation and anxiety negatively impact the postoperative experience and are risk factors for the development of chronic postsurgical pain and prolonged opioid use. Interventions aimed at reducing catastrophisation may be useful in improving patient outcomes, but retaining patient engagement with perioperative psychoeducation may also prove challenging (**N**).

☑ Preoperative psychoeducation may be cost effective from the perspective of reducing length of stay (**N**).

☑ The evidence that sensory and combined sensory-procedural information is effective in reducing procedure-related pain is equivocal and not sufficient to make recommendations (**U**).

☑ There is insufficient evidence to make a recommendation about the role of brief mindfulness-based interventions in acute pain (**N**).

7.2 | Transcutaneous electrical nerve stimulation

Transcutaneous electrical nerve stimulation (TENS) is the application of pulses of electrical current between two or more transcutaneous electrodes in order to stimulate cutaneous nerves. Unlike medications which only have dosage and route of administration as variables, TENS varies by anatomical location of electrodes, duration of usage, pulse amplitude, pulse frequency, pulse duration and pattern (eg burst, continuous or modulated). The variable ways in which TENS can be applied and lack of uniform reporting in studies makes pooling of results and interpretation of conflicting studies challenging. Furthermore, the blinding of such a physical intervention is difficult. Sham TENS varies in studies between a passive deactivated box connected to the patient where no stimulus is felt and devices which provide a short duration of therapeutic TENS. In a trial of inactive sham TENS vs 45 s transient sham TENS vs real TENS the investigators and patients were blinded 0% and 21% for inactive sham TENS, and 100% and 40% for transient sham TENS (Rakel 2010 **EH**). Thus, for the purposes of applying the Jadad score to studies we have not considered inactive TENS to be an adequate placebo.

TENS reduces acute pain (procedural and nonprocedural) vs no treatment (MD -19/100; 95%CI -27.3 to -10.8) (6 RCTs, n=413) and sham TENS (MD -24.6/100; 95%CI -31.79 to -17.46) (6 RCTs, n=376), with more participants achieving ≥50% reduction in pain vs sham TENS (RR 3.91; 95%CI 2.42 to 6.32) (4 RCTs, n=157) (Johnson 2015b **Level I** [Cochrane], 19 RCTs, n=1,346). These results are limited by a high risk of bias due to inadequate sample sizes in the trials and unsuccessful blinding including the use of non-TENS-naïve patients. Minor adverse effects reported were mild erythema, itching and participants disliking the TENS sensation (7 RCTs).

7.2.1 | Orthopaedic surgery

TENS vs placebo TENS reduces pain after total knee arthroplasty (TKA) at 12 h (SMD -0.26; 95%CI -0.44 to -0.08), 24 h (SMD -0.24; 95%CI -0.43 to -0.06) and 48 h (SMD -0.21; 95%CI -0.40 to -0.03) and opioid consumption at 12, 24, and 48 h (Li 2017b **Level I** [PRISMA], 5 RCTs, n=472). TENS also reduces the incidence of postoperative nausea by 9.8% and vomiting by 9.4%, but not the hospital LOS. The results are limited by small sample sizes in the trials; however, the quality of evidence is high. Repeated TENS provides long term pain reduction up to 6 mth postoperatively vs placebo TENS (2 RCTs, n=189) (Tedesco 2017 **Level I** [PRISMA], 39 RCTs, n=5,509). However, after anterior cruciate ligament repair, adding high-frequency transcutaneous TENS to exercise vs exercise alone did not improve pain and function in early rehabilitation (Forogh 2019 **Level II**, n=70, JS 4).

After rotator cuff repair TENS for four 45 min sessions/d for the first postoperative wk reduced pain at 12 h (3.1/10 ± 3.6 vs. 5.8/10 ± 4.4) and 1 wk (3.6/10 ± 2.1 vs. 5.8/10 ± 1.2) with less oxycodone 5 mg/paracetamol 325 mg requirements at 48 h (12.8 tablets ± 4.7 vs. 17.2 ± 6.3) and 7 d (25.2 tablets ± 10.0 vs. 33.8 ± 14.3) vs placebo TENS (Mahure 2017 **Level II**, n=37, JS 5).

Postoperative TENS applied to the surgical site for 15 min/d consecutively for 5 d after surgery did not reduce pain or analgesic use after Colles' Fracture vs placebo TENS (Lee 2015b **Level II**, n=36, JS 3).

7.2.2 | General and thoracic surgery

After thoracic surgery (thoracotomy or sternotomy), TENS reduces pain intensity vs sham TENS (thoracotomy -1.3/10; 95%CI -1.9 to -0.7; sternotomy -1.3/10; 95%CI -1.9 to -0.8) (Sbruzzi 2012

Level I [PRISMA], 11 RCTs, n=570). Subsequent RCT findings are consistent with these results (Sezen 2017 **Level II**, n=96, JS 1; Engen 2016 **Level II**, n=40, JS 3; Erden 2015 **Level II**, n=40, JS 1; Esteban Gonzalez 2015 **Level II**, n=50, JS 3). Although TENS was not more effective than a paravertebral (PVB) in relieving pain or reducing PCA usage following thoracotomy procedures, it had fewer adverse effects (Baki 2015 **Level II,** n=40, JS 1).

After liposuction, TENS vs placebo TENS reduced pain intensity (0/10 vs 4/10) and need for rescue analgesia at 6 h (95.2% vs. 47.6%) (da Silva 2015 **Level II**, n=42, JS 3).

After cessation of epidural analgesia following open colon resection, TENS reduced pain at 24 h post cessation (10/100 vs 23/100) vs placebo TENS, but no differences in quality of recovery or opioid use were found (Bjersa 2015 **Level II,** n=28, JS 5).

TENS (starting 1 h pre-operatively for inguinal hernia repair and ceased on induction) reduced pain at 2 h (3.5/10 ±1.5 vs 5.1/10 ±1.4) and 4 h (4.0/10 ±1.5 vs 4.8/10 ±1.4) and diclofenac use at 12 h (15.2% vs 39.4%), with no difference in other time points or anti-emetic use (Eidy 2016 **Level II**, n=66, JS 3).

7.2.3 | Procedural pain and prehospital analgesia

TENS reduced procedural pain (MD -2.7/10; 95%CI -1.6 to – 4.0) during carboxytherapy in patients with cellulite in the gluteal region vs placebo TENS (Sadala 2018 **Level II**, n=84, JS 1).

TENS used in the prehospital setting reduces pain intensity vs scores before TENS use (MD 38/100; 95%CI 28 to 44) and vs sham TENS (MD 33/100; 95%CI 21 to 44), as well as acute anxiety secondary to pain (Simpson 2014 **Level I** [PRISMA], 4 RCTs, n=261).

7.2.4 | Gynaecological surgery and obstetrics

In labour, TENS has no effect on pain, interventions or outcomes vs sham TENS (10 RCTs) or routine care (7 RCTs), when applied to the back (13 RCTs, n=1,150) or cranium (2 RCTs, n=140), with the exception of a reduction in reports of severe pain when applied to acupuncture points (2 RCTs, n=190) (Dowswell 2009 **Level I** [Cochrane], 17 RCTs, n=1,466). These findings of no analgesic effect are confirmed by two subsequent meta-analyses (Bedwell 2011 **Level I**, 14 RCTs, n=1,456 (14 RCTs overlap); Mello 2011 **Level I**, 9 RCTs, n=1,076 (3 RCTs overlap)).

Three subsequent RCTs not included in the above meta-analyses showed benefit from TENS in labour. A 30 min session of TENS over thoracic and sacrum area reduced immediate pain during the active phases of labour vs non-TENS control (Santana 2016 **Level II**, n =46, JS 3) or placebo TENS box (Baez-Suarez 2018 **Level II**, n =63, JS 3). TENS with varying high-frequency (80 to 100 Hz) was more effective than TENS of constant frequency (100 Hz) (Baez-Suarez 2018 **Level II**, n =63, JS 3). TENS produced sustained pain relief 4 h after the intervention and had shortened first-stage labour vs placebo or no TENS controls (Shahoei 2017 **Level II**, n=90, JS 1).

High-frequency TENS is effective in primary dysmenorrhoea (Proctor 2002 **Level I** [Cochrane], 7 RCTs, n=164). A subsequent systematic review did not add new information except for highlighting that quality of life is not reported in any RCT (Igwea 2016 **Level I**, 6 RCTs [TENS], n=247) (2 RCTs overlap). Subsequent RCTs reported similar results of daily TENS during menstrual bleeding; pain intensity, hours in pain and use of pain medications were reduced with inconsistent results on quality of life improvement vs placebo (Bai 2017 **Level II**, n=134, JS 3; Lauretti 2015 **Level II**, n=40, JS 3). TENS plus thermotherapy reduced period pain and duration in pain vs placebo TENS, without impact on analgesic use or quality of life (Lee 2015a **Level II**, n=115, JS 3).

7.2.5 | Migraine

TENS use in migraine reduces affected days/mth (SMD -0.5; 95%CI -0.7 to - 0.2) and pharmacological treatment intake (SMD -0.8; 95%CI -1.1 to - 0.4) (Tao 2018 **Level I** [PRISMA], 4 RCTs, n=161). Similarly, TENS over the supraorbital nerve (for 12 wk) reduced days in migraine and days using rescue medications among patients with refractory migraine and not responding to topiramate (Vikelis 2017 **Level IV**, n=35).

One 60 min TENS session reduced pain intensity of acute migraine attacks at one and 24 h after treatment by 50%, and two-thirds of the patients did not require rescue pain medication at 24 h (Chou 2017 **Level IV**, n=30).

7.2.6 | Musculoskeletal pain

One 30 min TENS session reduces acute low back pain in an emergency setting (MD – 28.0/100; 95%CI – 32.7 to −23.3) (1 RCT, n=63), whereas a course of TENS for 4-5 wk does not reduce sub-acute low back pain (MD −2.8/100; 95%CI −11.6 to 6.1) (2 RCTs, n=132) (Binny 2019 **Level I**, 3 RCTs, n=192). The evidence is limited by low quality and insufficient sample size.

One TENS session over shoulder myofascial trigger points increased pressure pain threshold and improved range of motion vs sham intervention (Takla 2018 **Level II**, n=70, JS 3). Burst-TENS was superior to medium-frequency, low intensity amplitude modulated frequency treatment.

7.2.7 | Neuropathic and phantom limb pain

In patients with herpes zoster, 10 to 15 TENS sessions reduced pain and incidence of PHN vs anti-viral agent alone and TENS/anti-viral agents (Stepanovic 2015 **Level II**, n=222, JS 1). However, the trial reporting quality is very low.

A systematic review of TENS in the treatment of phantom limb pain found no studies (Johnson 2015a **Level I** [Cochrane], 0 RCTs, n=0). However, a subsequent RCT found TENS vs mirror therapy equally effective at reducing pain scores from baseline (Barbin 2016 **Level I** [PRISMA], 1 RCT: Tilak 2016 **Level II**, n=25, JS 3).

KEY MESSAGES

1. Transcutaneous electrical nerve stimulation compared to sham reduces acute pain (procedural and nonprocedural) (**U**) (**Level I** [Cochrane Review]), including pain after thoracic surgery (**U**) (**Level I** [PRISMA), after total knee replacement (**N**) and in the prehospital setting (**N**) (**Level I** [PRISMA]).
2. High-frequency transcutaneous electrical nerve stimulation is effective in primary dysmenorrhoea (**U**) (**Level I** [Cochrane Review]).
3. Transcutaneous electrical nerve stimulation has no effect on pain, interventions or outcomes in labour with the exception of a reduction of reports of severe pain when applied to acupuncture points (**U**) (**Level I** [Cochrane Review]).
4. Transcutaneous electrical nerve stimulation used preventatively in migraine reduces attack frequency and medication use (**N**) (**Level I** [PRISMA])

7.3 | Acupuncture and acupressure

Acupuncture, originally a Chinese practice, involves inserting fine needles through the skin at specific points (acupoints) to cure disease or relieve pain. However, the term acupuncture is often interpreted broadly in many meta-analyses to incorporate all forms of acupoint stimulation including by electroacupuncture (EA: where a small electric current is passed between pairs of acupuncture needles), laser (laser acupuncture), pressure (acupressure), transcutaneous electrical acupoint stimulation (TEAS), chemical (capsicum plaster) or heat (moxibustion). Acupuncture needling or acupressure can be applied to the specific points on the ears and this form of technique is called auricular acupuncture (AA) or auriculotherapy. Even for traditional needle-based acupuncture angle, depth, location, rotation, duration and temperature of needles can all vary between studies.

A significant amount of the literature is published in the Chinese language; these references were excluded from this assessment in line with the agreed methodology, although many quoted meta-analyses incorporate Chinese language papers.

Similar to other physical therapies, blinding in acupuncture studies is difficult to achieve. Options such as non-penetrative needles (eg toothpicks) or using real acupuncture needles in non-acupoint locations might blind the patient, but do not blind the proceduralist and may be unintentionally therapeutic (Langevin 2011 **NR**). Furthermore, both experienced proceduralists and patients may expect to feel *De qi* (the Chinese expression for the sensation of tingling, heaviness and numbness associated with the needle application and rotation). Placebo acupuncture needles which look identical but retract to a short needle on use may also not fool proceduralists and, similar to using acupuncture in non-acupoint locations, might also be unintentionally therapeutic (Langevin 2011 **NR**). In one RCT, 68% of patients and 83% of proceduralists correctly guessed their allocation (vs an expected 50% if blinding was appropriate) (Vase 2015 **Level II**, n=67, JS 5). These blinding issues combined with extremely heterogeneous methods for heterogeneous conditions and often small sample sizes weaken the strength of recommendations from pooled results of these meta-analyses.

For paediatric specific acupuncture information see 10.11.2.

7.3.1 | Postoperative pain

The effect of acupuncture on postoperative pain has been examined in different surgical procedures, such as cardiac, abdominal, orthopaedic, gynaecological and obstetric surgery.

Overall, acupuncture (excluding AA), compared with sham controls reduces postoperative pain at 24 h (WMD -1.27/10; 95%CI -1.83 to -0.71) and opioid consumption at 24 h (SMD -0.72; 95%CI -1.21 to -0.22) (Wu 2016 **Level I**, 11 RCTs, n=682). A subgroup analysis found TEAS (5 RCTs, n=305) reduces both pain and opioid consumption, needle acupuncture (2 RCTs, n=165) reduces pain, but EA has no effect (4 RCTs, n=212).

In a prior meta-analysis (9 RCTs overlap), all forms of acupuncture (body or auricular points) reduce postoperative pain (at 24 h) vs both sham controls (SMD -0.72; 95% CI -1.03 to -0.41) (23 RCTs, n=1,284) and standard treatment (SMD -1.05; 95% CI -1.44 to -0.67) (20 RCTs, n=1,227) (Liu 2015a **Level I**, 59 RCTS, n=4,578). Opioid analgesia use decreases (ME −4.99mg; 95%CI −7.51 to −2.47) (6 RCTs, n=399) over an unspecified time period.

Similar findings were reported for a number of specific postoperative settings as outlined below.

7.3.1.1 | Abdominal and general surgery

After open abdominal surgeries (including Caesarean section, gynaecological and general surgical), acupuncture vs sham or no treatment reduces postoperative pain at rest (≈-7 to -13/100) (18 RCTs, n=1,088), and with movement (≈-4 to -26/100) (6 RCTs, n=436) at 4 to 48 h, and reduces opioid consumption at 24 h (WMD -9.17 mg; 95%CI -12.47 to - 5.87) (13 RCTs, n=806) (Zhu 2019 **Level I** [PRISMA], 35 RCTs, n=2,015). Pain scores are less at 4 h in patients who receive distal acupuncture vs peri-incisional acupuncture. However, reduction of opioids at 24 h is four times more in the peri-incisional acupuncture group than that in distal acupuncture group. Distal acupuncture reduces the incidence of post-operative nausea and dizziness; however, this data was not reported in the studies of peri-incisional acupuncture.

Haemorrhoidectomy

After haemorrhoidectomy, 30 min EA around the surgical site vs sham reduced pain intensity at 6 h, 24 h and during defecation, with no difference in eating, sleeping and anxiety (Wu 2018 **Level II**, n=72, JS 3).

Hernia repair

Combined pre-emptive acupuncture on body points and intraoperative acupuncture at the incision site for open inguinal hernia repair reduced postoperative pain intensity at 0.5 to 6 h postoperatively as well as PCA requirements and dizziness (Taghavi 2013 **Level II**, n=90, JS 1). Pre- and intraoperative EA resulted in a late reduction in pain scores at POD 4 and 7 only (Dias 2010 **Level II**, n=33, JS 5). For inguinal herniorrhaphy under spinal anaesthesia, preoperative acupuncture on body points enhanced intraoperative sedation and reduced postoperative pain intensity and opioid requirements (Parthasarathy 2009 **Level II**, n=50, JS 3). Preoperative and intra-operative EA had similar pain reduction and opioid sparing effect in inguinal hernia (mesh) repair under general anaesthesia (Dalamagka 2015, **Level II**, n=54, JS 2).

Laparoscopic Surgery

Intraoperative EA for laparoscopic cholecystectomy had no impact on pain, PCA use or PONV vs no acupuncture (El-Rakshy 2009 **Level II**, n=107, JS 5). However, one to two sessions of postoperative acupuncture reduced shoulder pain in patients with established shoulder pain after laparoscopic abdominal surgery (mostly cholecystectomy) (mean reduction 6.4/10 [SD 2.3]) (Kreindler 2014 **Level IV**, n=25).

Appendicectomy

Sustained acupressure with an 'acuband' after open appendicectomy was better than sham control in relieving postoperative pain (Adib-Hajbaghery 2013 **Level II**, n=70, JS 3).

7.3.1.2 | Orthopaedic surgery

Lumbar spinal surgery

Needle acupuncture after lumbar spinal surgery reduces pain at 24 h (SMD -0.67; 95%CI -1.04 to -0.31) (Cho 2015 **Level I** [PRISMA], 5 RCTs, n=480). In addition to PCA, postoperative AA and TEAS improved pain scores vs sham only, and reduced opioid use vs both sham and control groups (Chung 2014 **Level II**, n=135, JS 3). During the rehabilitation phase, EA in addition to standard medical and physiotherapy care, reduced disability at 2 mth postoperatively, but did not reduce pain or improve quality of life (Heo 2018 **Level II**, n=39, JS 3).

Total Knee Arthroplasty

Perioperative acupuncture for TKA reduces pain at POD 2 (WM -1.14/10; 95%CI −1.90 to −0.38) and delayed time to first PCA use (WMD 46 min; 95%CI 20.8 to 71.5) (Tedesco 2017 **Level I** [PRISMA], 3 RCTs, n=230), with no effect on opioid consumption within the first 48 h. Acupressure may improve range of motion vs sham controls (He 2013 **Level II**, n=90, JS 5; Chang 2012 **Level II**, n=68, JS 5). During the rehabilitation phase, acupuncture in addition to exercise was not better than exercise alone either in reducing pain or improving function at 3 mth post TKA (Petersen 2018 **Level II**, n=172, JS 3).

Total Hip Arthroplasty

Perioperative AA or acupressure continuing into the postoperative period reduces pain after THA at 12 h, 24 h, 48 h, 72 h, POD 5, POD 7 (1 to 6 RCTs) and intraoperative fentanyl use (SMD -0.73; 95%CI -1.09 to -0.36) (3 RCTs, n=250) (Ye 2019 **Level I**, 9 RCTs, n=605). There were no differences in the time to first analgesic request or PONV.

Shoulder Surgery

One session of postoperative acupuncture performed in PACU reduced pain after arthroscopic shoulder surgery on POD1 and improved sleep quality vs non-acupuncture control (Ward 2013 **Level III-1**, n=22).

7.3.1.3 | Cardiac & thoracic surgery

Cardiac surgery

For cardiac surgery, EA started 20 to 30 min prior to induction of GA may improve some perioperative outcomes, but has no impact on opioid requirements (Asmussen 2019 **Level I** [PRISMA], 7 RCTs, n=321).

Preoperative EA administered 12–18 h before cardiac surgery (including myocardial revascularisation and valve replacement) reduced postoperative pain intensity (2.5/10 ± 1.1 vs 4.0/10 ± 2.0) and PCA fentanyl use by 41% vs placebo (Coura 2011 **Level II**, n=22, JS 5). Postoperative acupressure reduced pain intensity after cardiac surgery via median sternotomy and improved lung function vs acupressure to nonspecific points or no acupressure control (Maimer 2013 **Level II**, n=100, JS 5). When acupuncture was repeated daily for 7 d, the benefit for pain and lung function accumulated and improved over time (Colak 2010 **Level II**, n=30, JS 3).

Thoracic surgery

Repeated postoperative EA (delivered distant to the surgery site over three days) reduced post-thoracic pain at 2, 24, 48 and 72 h and breakthrough pethidine consumption (9.2 mg ± 2.8 vs 11.5 mg ± 1.8) (Chen 2016 **Level II**, n=92, JS 3). EA also reduced nausea (21.7% vs 47.8%) but not vomiting. There was shortened time to first flatus (24.3 h ± 8.2 vs 35.7 h ± 7.76) and defaecation (42.7 h ± 13.9 vs 59.2 h ± 11.3) n=).

7.3.1.4 | Gynaecological and obstetric surgery

Hysterectomy

After open hysterectomy, EA improved postoperative analgesia over 24 h vs control and sham acupuncture (Lee 2011 **Level II**, n=47, JS 3). Postoperative auricular EA applied ≈24 h after open hysterectomy reduced pain at rest and on movement vs control and sham stimulation (Tsang 2011 **Level II**, n=48, JS 5).

EA during surgery under general anaesthesia provided no benefit vs no acupuncture for pain, PCA opioid use or PONV after open hysterectomy and laparoscopic cholecystectomy (El-Rakshy 2009 **Level II**, n=107, JS 5).

Oncological surgery

After open gynaecological surgery for malignancy, EA was superior to traditional acupuncture in relieving pain initially but not at 48 h (Gavronsky 2012 **Level II**, n=20, JS 1).

Laparoscopic gynaecological surgery

Auricular EA did not affect pain or opioid requirements after laparoscopic gynaecological surgery (Holzer 2011 **Level II**, n=40, JS 5); whereas EA to body points delivered 24 h prior to surgery or during surgery reduced pain and PONV (Li 2017d **Level II**, n=40, JS 3; Praveena Seevaunnamtum 2016 **Level II**, n=64, JS 3).

Oocyte retrieval

For oocyte retrieval, conscious sedation plus EA reduces procedural and postoperative pain more than sedation plus placebo, or sedation alone (Kwan 2018 **Level I** [Cochrane], 6 RCTs, n=1,159). However, a paracervical block achieves lower procedural pain scores than EA (4 RCTs, n=781).

Caesarean section

After Caesarean section, postoperative EA and acupuncture reduced pain scores and PCA requirements for up to 2 h (Wu 2009 **Level II**, n=60, JS 3).

7.3.1.5 | Ear, nose and throat surgery

For tonsillectomy, perioperative acupuncture vs sham or no therapy reduces pain for the first 48 h, postoperative analgesia requirements and PONV (Cho 2016 **Level I** [PRISMA], 12 RCTs, n=1,025 [11 RCTs in children & adolescents, 1 in adults]).

Battlefield auricular acupressure vs usual care reduces post-tonsillectomy pain in adults at discharge, with no effect on pain or opioid use at POD 10 (Plunkett 2018 **Level II**, n=95, JS 3).

7.3.1.6 | Neurosurgery

TEAS vs placebo reduces post craniotomy pain, PCA fentanyl use from 0 to 6 h and reduces dizziness and feelings of "a full head" up to 24 h (Tsaousi 2017 **Level I** [PRISMA], 2 RCTs [TEAS], n=176).

7.3.2 | Other acute pain states

7.3.2.1 | Emergency department and acute trauma setting

AA including acupressure improves pain relief vs control treatment for pain due to acute hip fracture (1 RCT), acute biliary colic (1 RCT) and acute burn and acute emergency conditions (SMD 1.35; 95%CI 0.08 to 2.64) (2 RCTs, n=111) (Asher 2010 **Level I** [PRISMA], 4 RCTs [acute pain], n=197). These findings were confirmed in a later meta-analysis which found AA vs sham or standard care reduces pain (WMD -2.6/10; 95%CI -2.00 to -3.22) but had a variable effect on analgesic use with only 1 of 3 studies reporting a difference (Jan 2017a **Level I** [PRISMA], 4 RCTs, n=281) (3 RCTs overlap). Adverse effects of AA were documented in only 2 studies in which minor pain was experienced in 2 patients. It takes about 2 to 10 min to apply the treatment at the cost of AU$7.50 per patient (Jan 2017b **Level I** [PRISMA], 4 RCTs, n=281).

Needle acupuncture on the body was faster (16 ± 8 min vs 28 ± 14 min) and more successful (92% vs 78%) at reducing pain by 50% with less nausea and vomiting vs IV morphine control (mean dose 0.17 mg/kg ± 0.08) (Grissa 2016 **Level II**, n=300 [46% abdominal pain, 54% musculoskeletal or other pain], JS 3). Similarly, for renal colic a 30 min acupuncture session vs

titrated IV morphine achieved a 50% pain reduction faster (14 min vs 28), with far fewer patients experiencing side effects (acupuncture 3/54 vs morphine 42/61) (Beltaief 2018, **Level II**, n=115, JS 3). An RCT of acupuncture vs acupuncture/pharmacotherapy vs pharmacotherapy alone for back pain, ankle sprain and migraine found no difference between pain scores at 1 h or satisfaction at 1 h or 24 h (Cohen 2017 **Level II**, n=528, JS 3). The acupuncture alone group required more rescue analgesia vs the pharmacology alone and combination groups, with lower hospital admission rate in the combination group.

Acupuncture reduced pain (by 2.3/10) and nausea (by 1.2/6) in patients with acute pain vs retrospectively matched controls, with a high satisfaction rate (98%) (Zhang 2014 **Level III-3**, n=400 [59% musculoskeletal, 25% abdominal pain]). Acupuncture treatment provided before medical consultation reduced the staff time spent managing the patient vs acupuncture given after medical consultation.

Acupuncture vs sham reduced pain on movement in bed and cough after rib fracture but not pain on deep breathing (Ho 2014 **Level II**, n=58, JS 5). Acupressure reduced acute musculoskeletal pain due to sports injuries vs sham or no acupressure (Macznik 2017 **Level II**, n=79, JS 3).

In acute pain due to sports injury, athletes had significant pain reduction (4 to 8/10) after auricular acupuncture treatment (deWeber 2011 **Level IV**, n=8).

Acupressure performed during prehospital transport led to better pain relief vs sham acupressure after hip fracture (auricular) (Barker 2006 **Level II**, n=38, JS 5) and radial fracture (Lang 2007 **Level II**, n=32, JS 5), and after minor trauma vs sham and no acupressure (Kober 2002 **Level II**, n=60, JS 5).

7.3.2.2 | Acute back pain

Compared to sham acupuncture, one session of acupuncture reduces pain intensity (MD -9.38/100; 95%CI -17.00 to -1.76) (2 RCTs, n=100) but not function or disability in acute back pain (3 RCTs, n=148) (Lee 2013 **Level I** [PRISMA], 11 RCTs, n=1,139). Slightly more patients improved with acupuncture than NSAIDs (RR 1.11; 95%CI 1.06 to 1.16) (5 RCTs, n=662).

In a large well-designed RCT, five sessions of acupuncture over 14 d were added to conventional treatment for acute low-back pain (Vas 2012 **Level II**, n=275, JS 5). Acupuncture was more effective in reducing pain and analgesic use and improving work readiness vs conventional treatment alone; but there was little difference between real acupuncture, sham acupuncture (penetrating) and placebo acupuncture (nonpenetrating). One session of acupuncture with concurrent gentle exercise produced better analgesia for severely disabling acute low-back pain (Oswestry Disability Index [ODI] value ≥60%) than diclofenac (75 mg IM) (Shin 2013 **Level II**, n=58, JS 3). Patients in the acupuncture group had less pain at 30 min after treatment (MD 3.12/10; 95%CI 2.26 to 3.98), much improved function (decreased ODI by 33%; 95%CI 27 to 39) and fewer hospital admissions (66 vs 93%). The pain reduction was maintained at 2 wk and 4 wk follow-up.

Battlefield AA plus standard therapy has better pain reduction for acute low back pain in ED over standard care alone with no differences in functional recovery (Fox 2018 **Level II**, n=30, JS 3). Acupuncture with concurrent lumbar exercise has better sustained pain reduction in acute lumbar sprain than conventional acupuncture, sham intervention or TENS at 24 h (Lin 2016 **Level II**, n=60, JS 3). Similar results are shown in a cohort study (Liu 2015c **Level III-2**, n=74).

Acupuncture plus spinal manipulation has similar pain reduction in sub-acute low back pain vs acupuncture alone or spinal manipulation alone (Kizhakkeveettil 2017 **Level II**, n=101, JS 3).

7.3.2.3 | Labour and post-partum pain

With regard to use of acupuncture in labour (Smith 2020 **Level I** [Cochrane], 28 RCTs, n=3,960):

- Acupuncture vs sham does not reduce pain scores (2 RCTs, n=325), but does increase satisfaction with pain relief (RR 2.38; 95%CI 1.78 to 3.19) (1 RCT, n=150) and decrease use of pharmacological analgesia (RR 0.75; 95%CI 0.63 to 0.89);
- Acupuncture vs usual care reduces pain scores (4 RCTs, n=495) and use of pharmacological analgesia (6 RCTs, n=1,059) but does not improve satisfaction (2 RCTs, n=343).
- Acupuncture vs no treatment reduces pain scores (1 RCT, n=163);
- Acupuncture vs water injection did not reduce use of pharmacological analgesia (1 RCT, n=128);
- Acupressure vs sham lowered VAS (MD -1.93/10; 95%CI -3.31 to -0.55) but had no effect on use of pharmacological analgesia (6 RCTs, n=472);
- Acupressure vs usual care reduced VAS (SD -1.07; 95%CI -1.45 to -0.69) (8 RCTs, n=620) and improved satisfaction (1 RCT, n=105);
- Acupressure vs both placebo and usual care reduced VAS (-0.42 SD; 95%CI -0.65 to -0.18) (2 RCTs, n=322) and marginally increased satisfaction with analgesia (1 RCT, n=212).

There was no effect on Caesarean section rate for all interventions. No study was at a low risk of bias on all domains.

Note: reversal of conclusion
This reverses the Level I key message in the previous edition of this document; a preceding meta-analysis had described a reduction of Caesarean section rate by use of acupuncture.

A critical review (Levett 2014 **NR**) of the previous iteration of this and another meta-analysis (Cho 2010 **Level I**, [PRISMA], 10 RCTs, n=2,038) suggests that these meta-analyses may compare very different approaches in very different settings, in particular by comparing trials of efficacy with trials of effectiveness.

TEAS provided inferior analgesia in labour vs epidural (SMD -53.00/100; 95%CI -58 to -48) or tramadol/ondansetron PCA but was superior to placebo (Anim-Somuah 2018 **Level I** [Cochrane], 1 RCT: Liu 2015b **Level II**, n=120, JS 3).

Patients with mastitis are less likely to have severe symptoms 5 d after acupuncture in 1 of 2 RCTs (Mangesi 2016 **Level I** [Cochrane], 2 RCTs, n=293).

Auricular acupressure (by taping seeds to the ear) did not reduce acute postpartum perineal pain in women with 1st or 2nd degree tears or episiotomies (Kwan 2014 **Level II**, n=266, JS 3) contrasting with a previous study where wrist-ankle needle acupuncture for perineal pain after episiotomy reduced requirements for rescue analgesia vs controls (Marra 2011 **Level III-1**, n=42) (See also section 9.1.3.5).

7.3.2.4 | Dysmenorrhoea

Acupuncture may reduce pain in primary dysmenorrhoea vs NSAIDs (14 RCTs, n=850) or no-acupuncture controls (6 RCTs, n=384), but not vs sham or placebo controls (6 RCTs, n=477); whereas acupressure reduces pain vs sham or placebo control (5 RCTs, n=538), but not vs NSAIDs (1 RCT, n=136) or no treatment (2 RCTs, n=140) (Smith 2016 **Level I** [Cochrane], 42 RCTs, n=4,640). Only one of the 42 RCTs was considered of low risk of bias in all domains and generally data was unsuitable for pooling due to heterogeneity.

A subsequent network meta-analysis found acupuncture may be more effective than NSAIDs in reducing the risk of pain episodes of primary dysmenorrhoea, with EA being the most effective (Luo 2019a **Level I** [NMA]**,** 17 RCTs, n=1,511). Another systematic review found EA more effective than needle acupuncture or NSAIDs (Woo 2018 **Level I** [PRISMA], 60 RCTs, n=5,901) (6 RCT overlap). While, another meta-analysis found acupuncture (pooled all types) reduces symptom severity scores (6 RCTs, n=621) but not pain scores (2 RCTs, n=168) (Xu 2017 **Level I** [PRISMA], 19 RCTs, n=1,690) (5 RCTs overlap with Smith 2016).

Acupressure to SP6 (a lower leg acupoint) delivered by trained therapists reduces pain in primary dysmenorrhoea vs controls and the effect lasts for 3 h (5 RCTs), whereas patient self-administered acupressure does not reduce pain immediately, and takes 3 mth to be effective (3 RCTs) (Abaraogu 2016 **Level III-1 SR** [PRISMA], 5 RCTS & 1 study, n=461).

7.3.2.5 | Dental pain

Acupuncture may be useful for pain during dental procedures (Ernst 1998 **Level I**, 16 RCTs, n=941). Acupuncture reduced dental pain from 6.6/10 to ≈1.0/10 in an ED case series, with 119/120 patients responding (Grillo 2014 **Level IV**, n=120).

7.3.2.6 | Acute neuropathic pain

In severe pain due to acute herpes zoster (NRS >7/10), acupuncture was as effective as standard pharmacological treatment (pregabalin, local anaesthetics and TD buprenorphine or oral oxycodone) at 4 wk (Ursini 2011 **Level II**, n=102, JS 3).

7.3.2.7 | Headache

Acupuncture (at least 6 sessions) provides clinically relevant improvement in pain for tension type headache (TTH) over 3 mth vs standard care (2 RCTs, n=1,472), but only minimal clinical improvement vs sham treatment (5 RCTs, n=703) (Linde 2016a **Level I** [Cochrane], 12 RCTs, n=2,349).

Similarly, acupuncture reduces migraine frequency at 3 mth vs no treatment or routine care (4 RCTs, n=2,199), but only minor improvements were seen vs sham treatments (14 RCTs, n=1,825) (Linde 2016b **Level I** [Cochrane], 22 RCTs, n=4,985). Acupuncture reported fewer adverse effects (5 RCTs, n=931) vs pharmacological prophylaxis and acupuncture was slightly superior at 3 mth but not at 6 mth (3 RCTs, n=739). A subsequent RCT also found a prophylactic effect of EA (5 sessions per wk for 12 wk) on migraine (Li 2017a, **Level II**, n=61, JS 3).

In the guidelines for headache by the National Clinical Guideline Centre of the UK, 10 sessions of acupuncture are recommended for TTH treatment and as a prophylaxis, and for migraine when prophylactic medications are ineffective (NICE 2012 **GL**).

Acupuncture vs sham as a treatment for acute migraine attacks reduced pain intensity, but had no impact on pain freedom at or beyond 24 h or risk of recurrence (Wang 2012 **Level II**, n=150, JS 5).

AA was marginally better than sham acupuncture at 15, 30, 45 and 60 min in reducing migraine pain and recurrent analgesia usage within 24 h occurred in 1/30 of AA vs 13/30 of sham patients (Farahmand 2018 **Level II**, n=60, JS 3).

7.3.2.8 | Other painful conditions

Battlefield AA reduced sore throat vs standard therapy (Moss 2015, **Level II**, n=54, JS 3). Acupressure also reduced procedure pain and anxiety related to venepuncture over sham or standard care (Hosseinabadi 2015, **Level II**, n=187, JS 2).

Acupuncture may reduce post-stroke pain (MD −1.59/10; 95%CI −1.86 to −1.32]) when added to routine rehabilitation (25 RCTs), however with low certainty due to poor study quality (Liu 2019 **Level I** [PRISMA], 38 RCTs, n=3,184).

KEY MESSAGES

1. Acupuncture and acupressure for labour pain may reduce pain, use of pharmacological pain relief and increase satisfaction with pain management versus standard care or placebo (**Q**) (**Level I** [Cochrane Review]); Caesarean section rates are unchanged (**R**) (**Level I** [Cochrane Review]).
2. For oocyte retrieval, electroacupuncture plus sedation reduced procedural and postoperative pain compared with sedation plus placebo or sedation alone (**U**), but may be inferior to paracervical block plus sedation (**Q**) (**Level I** [Cochrane Review]).
3. Acupuncture or acupressure may be effective in the treatment of primary dysmenorrhoea (**S**) (**Level I** [Cochrane Review]).
4. Acupuncture may reduce the frequency of tension-type headaches and migraine (**U**) (**Level I** [Cochrane Review]); in migraine, it may be better tolerated than pharmacological prophylaxis (**N**) (**Level I** [Cochrane Review]).
5. Acupuncture may be effective in a variety of acute pain conditions in the emergency department setting (**S**) (**Level I** [PRISMA]) including back pain (**N**) (**Level I** [PRISMA])
6. Acupuncture by a variety of techniques may reduce postoperative pain and opioid consumption for a variety of surgical types (**S**) (**Level I**); specifically, the benefit may occur after lumbar spinal surgery (**U**) (**Level I** [PRISMA]), total knee arthroplasty (**U**) (**Level I** [PRISMA]), total hip arthroplasty (**N**) (**Level I**) and craniotomy (**N**) (**Level I** [PRISMA]).
7. There is no difference between distant acupuncture and acupuncture at the incisional site for open abdominal surgery (**S**) (**Level I** [PRISMA]).
8. Acupuncture may reduce post-stroke pain (**N**) (**Level I** [PRISMA]).

7.4 | Photobiomodulation

Photobiomodulation (PBM), previously called low-level laser therapy (LLLT), is the application of non-thermal laser in the red and near-infrared light wave lengths (600 to 1,000 nm) to tissue in order to produce biological effects. Light-matter interactions are well appreciated to occur where the encounter between a photon (or series of photons) causes the biology to enter an altered energetic state which causes an altered function. Sometimes this is destructive (eg UV and DNA), other times the effects are transient. PBM has multiple potential mechanisms of action including the displacement of inhibitory nitric oxide from cytochrome c oxidase increasing mitochondrial ATP production as well as interaction with light-sensitive ion channels, ultimately resulting in reversible inhibition of peripheral nerve conduction (Chow 2011 **SR EH BS**, 44 studies [18 human, 26 animal]) and reduced levels of prostaglandin E2 and inflammatory mediators (de Freitas 2016 **NR**). Studies vary in both total energy (J), energy density (J/cm^2) and wavelength of light used.

7.4.1 | Mucositis and stomatitis

A systematic review of PBM for recurrent aphthous stomatitis could not carry out a meta-analysis, but reports pain relief in 5 of 6 RCTs immediately after treatment, and 7 of 9 RCTs in the days following treatment (Suter 2017 **Level I**, 10 RCTs, n=512).

PBM may be effective in reducing pain intensity, severity and duration of mucositis based on moderate evidence (Anschau 2019 **Level I** [PRISMA], 5 RCTs, n=315). This is in line with findings of two small low-quality RCTs not included in the meta-analysis (Abramoff 2008 **Level II**, n=11, JS 2; Arora 2008 **Level II**, n=28, JS 2).

PBM used prophylactically reduces the risk of severe mucositis and pain in patients with cancer or undergoing hematopoietic stem cell transplantation (Oberoi 2014 **Level I** [PRISMA], 18 RCTs, n=1,144). This approach is recommended in a specific clinical practice guideline (Zadik 2019 **GL**).

For more details see also Section 8.9.8.2 and for paediatric mucositis see Section 10.8.3.1.

7.4.2 | Maxillofacial, ENT and dental surgery

After surgical removal of third molars, PBM reduces postoperative pain on POD 2 (WMD -1.42/10; 95%CI -2.18 to -0.67) (11 studies, n=434) and less on POD 7 (WMD -0.59/10; 95%CI -0.96 to -0.22) (10 studies, n=350) (Dawdy 2017 **Level III-2 SR [**PRISMA], 11 studies, n=434). However, studies were assessed as high risk of bias in multiple domains and had high heterogeneity. Similarly, an earlier meta-analysis finds reductions in pain from POD 1 to POD 3 after 3rd molar surgery (He 2015 **Level III-2** [PRISMA], 4 RCTs, n=150) (3 RCTs overlap). A subsequent study also showed reductions in postprocedural pain (Singh 2019 **Level III-2**, n=25).

After Le Fort I osteotomy in patients acting as their own controls, PBM vs no treatment reduced pain on the irradiated side of the face at 24 and 72 h after surgery, but not during the immediate post-operative assessment and there was no pain on either side by POD 7 (Bittencourt 2017 **Level III-2 SR** [PRISMA], 1 study: Gasperini 2014 **Level III-2**, n=10).

After orthodontic treatment with fixed appliances in children and young adults, 11 of 13 studies reported a reduction in acute pain, however, no meta-analysis was performed and studies were broadly of low quality (Sonesson 2016 **Level III-1 SR** [PRISMA], 13 studies, n=333).

Paracetamol usage in children undergoing secondary palatal surgery was reduced by PBM (970 nm, 2 W, 35 J/cm^2) vs undescribed placebo on POD 2 and POD 3 (Ezzat 2016 **Level II**, n=20, JS 2).

See also orofacial pain in Section 8.6.7.

7.4.2.1 | Tonsillectomy

Immediately after tonsillectomy in 5 to 15 y old children, intraoperative PBM (685 nm, 4 J/cm^2) vs no treatment reduced pain scores on POD 1, POD 2, POD 4 and POD 5 as well as the need for breakthrough non-opioid analgesic on POD 1 (45% vs 100%) (Neiva 2010, **Level II**, n=18, JS 1).

Intraoperative PBM (980 nm, 4 J/cm^2) applied immediately after tonsillectomy in adults vs unpowered probe application reduced mean pain scores in the first 24 h (1.43/4 vs 2.11/4) and need for rescue opioids (6.6% vs 33.3%) (Aghamohammadi 2013 **Level II**, n=60, JS 1).

7.4.2.2 | Vascular access

PBM reduces the incidence of needle pain during arteriovenous fistulas access vs placebo (RR 0.08; 95%CI 0.06 to 0.10) (Wan 2017 **Level I**, 3 RCTs, n=186), however, heterogeneity was reported as high.

7.4.2.3 | Cardiothoracic surgery

PBM (660 nm, 6 J/cm^2, 2.4 J) reduced sternotomy pain after CABG surgery on POD 6 and POD 8 vs both placebo and usual care groups, but all groups had negligible pain 1 mth after surgery (Fernandes 2017 **Level II**, n=90, JS 4).

After off-pump CABG surgery, pain was reduced post PBM (980 nm, 10 J/cm^2, 150 J; commenced 30 min post-extubation) at 1 h and 24 h vs pre-PBM levels (Karlekar 2015 **Level IV**, n=100).

7.4.2.4 | Musculoskeletal pain and orthopaedic surgery

After the first presentation with acute ankle sprain, two sessions of PBM (635 nm, 4.5 and 9 J/cm^2), in addition to standard care of rest, icing, compression and elevation, did not reduce pain at 10 d or 6 wk vs standard care (Calin 2019, **Level II**, n=19, JS 2).

After tibial fracture surgery, PBM (808 nm, 6 J/cm^2 and 650 nm, 3 J/cm^2) reduced pain scores from 2 h to 24 h and IV pethidine administration over 24 h (51.6 mg ± 29.5 vs 89.3 ± 35.5) (Nesioonpour 2014b **Level II**, n=54, JS 1).

In patients undergoing radius fracture fixation under intravenous regional anaesthesia (IVRA) the addition of cervical and affected extremity PBM (808 nm) reduced procedural and post procedural pain and opioid consumption (Nesioonpour 2014a **Level II**, n=48, JS 3).

After total hip arthroplasty, PBM (905 nm, 875 nm and 640 nm, total 201.5 J) reduced pain scores from baseline more vs placebo, as well as IL-8 and TNF-α concentrations (Langella 2018 **Level II**, n=18, JS 5). However, pain scores were higher in the PBM group initially and absolute pain scores were not reported in the study.

7.4.2.5 | Labour, puerperium and Caesarean section

After episiotomy, PBM (780 nm or 660 nm, 8.8 J/cm^2, 1.05 J) did not reduce pain immediately or at 30 min (Santos Jde 2012 **Level II**, n=114, JS 5). A subsequent RCT had similar findings with PBM (780 nm, 5 J/cm^2, 5.4 J) applied 6-10 h postpartum for episiotomy being ineffective for pain (Alvarenga 2017 **Level II**, n=54, JS 5).

PBM (650 nm and 804 nm, total 21 to 30 J) after Caesarean section under spinal reduced pain at 1 h to 24 h and pethidine consumption (57.83 mg ± 29.57 vs 107.78 mg ± 34.28) and prolonged time to first analgesia request (226.5 min ± 14.56 vs 88.5 min ± 15.78) (Poursalehan 2018 **Level II**, n=80, JS 2).

7.4.2.6 | Other surgery

After breast augmentation, application of pre-incision PBM (630 to 640 nm) reduced pain scores at 24 h (21.4/100 vs 36.8) but not at 7 d to 28 d (Jackson 2009 **Level II**, n=104, JS 2).

Post open inguinal herniorrhaphy, PBM (830 nm, 13 J/cm^2, 10.4 J) on POD 1 , POD 3 and POD 7 did not reduce pain scores at 6 mth (Carvalho 2010, **Level II**, n=28, JS 3).

KEY MESSAGES

1. Photobiomodulation may be effective for both prophylaxis and treatment of mucositis in oncology patients (**S**) (**Level I** [PRISMA]).
2. Photobiomodulation may reduce pain after 3rd molar extraction (**N**) (**Level I** [PRISMA]).
3. Needle related pain after arteriovenous fistula access may be reduced by photobiomodulation (**N**) (**Level I**)
4. After episiotomy, photobiomodulation may not reduce pain (**N**) (**Level II**).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Photobiomodulation may have a role in acute postsurgical pain management, however evidence is currently insufficient to make any furrher recommendations (**N**).

7.5 | Physical therapies

Physical therapies for acute pain management are typically adjunctive to the psychological and pharmacological treatments discussed elsewhere in this book. The physical therapies covered in this section include the active therapies of exercise, prehabilitation and rehabilitation as well as the passive therapies of massage and other manual therapies, warming and cooling. Other passive physical therapies discussed elsewhere include TENS (see Section 7.2), acupuncture (see Section 7.3) and PBM (low-level laser therapy [LLLT]) (see Section 7.4). Specific conditions addressed elsewhere include acute back pain (see Section 8.7) and acute musculoskeletal pain (see Section 8.8). Some therapies such as aromatherapy which are not considered core physical therapies for acute pain are not covered in this chapter, but in complementary and alternative medicine (see Section 4.14.3).

Evidence for the benefits and harm of physical therapies in acute pain management is variable. The use of physical therapies for acute pain management should reflect contemporary practice guidelines promoting the use of active self-management (including exercise) rather than a sole focus on passive therapies. Physical therapies typically incorporate contemporary education on pain, including the provision of clear and meaningful information and advice about the management of acute pain and this component is covered under education (see Section 3.1).

The evidence for physical therapies is currently limited by wide heterogeneity of multimodal interventions and conditions, limited studies with small sample sizes and difficulties with consistent blinding leading to a risk of bias.

This section focuses on the effect of physical therapies on pain outcomes; other benefits may be present but have not been thoroughly reviewed.

7.5.1 | Active exercise-based therapies

7.5.1.1 | Exercise

Total joint arthroplasty

Exercises carried out preoperatively before total knee arthroplasty (TKA) do not improve postoperative pain at 4 wk (2 RCTs, n=224) or 8 wk (3 RCTs, n=242) vs standard interventions (Umehara 2018 **Level I**, 27 RCTs**,** n=2,432). An exercise intervention in addition to standard postoperative interventions for 8 wk after discharge, reduces pain relative to standard postoperative interventions alone (SMD −0.65; 95%CI −1.22 to −0.08) and improvement in function (eg stiffness, extension strength, knee flexion range and gait speed). No differences are found for implementation of early vs late postoperative exercise for pain outcomes at 4 wk (2 RCTs, n=573) or 8 wk (2 RCTs, n=318) (Umehara 2018 **Level I**, 27 RCTs**,** n=2,432).

After total hip replacement (THA), adding supervised exercise (two 30 to 40 min sessions/wk for 10 wk) did not further increase leg extension, but improved walking speed and stair climbing speed vs non-supervised exercise alone (Hansen 2019 **Level I** [PRISMA], 1 RCT: Mikkelsen 2014, **Level II**, n=60, JS 3).

Meniscal lesions

There is no significant difference in knee pain between exercise therapy and meniscectomy for patients with a degenerative meniscal lesion in the short term (2 studies, n=125) (Swart 2016, **Level III-1 SR**, 12 studies, n=594). Even at two to three mth follow-up, exercise or an exercise-

based physical therapy program vs arthroscopic partial meniscectomy results in no difference in pain (3 RCTs, n=344) (van de Graaf 2016, **Level I** [PRISMA], 6 RCTs, n=773).

The outcomes of exercise therapy versus no exercise therapy after meniscectomy at <3 mth are conflicting (2 RCTs, n=125), with one study finding a significant benefit of exercise on knee pain, while the other did not; however, data could not be pooled due to the measurement of pain at different time points (Swart 2016 **Level I**, **Level III-1 SR**, 12 studies, n=594).

Anterior cruciate ligament (ACL) reconstruction

Immediate postoperative weight bearing significantly decreased the proportion of patients reporting pain symptoms 2 wk after anterior cruciate ligament (ACL) reconstruction and did not increase joint laxity vs patients who had 2 wk delayed weight bearing (Secrist 2016 **Level I** [PRISMA] 1 RCT: Tyler 1998 **Level II**, n=45, JS 2).

Ankle sprains

Compared with home exercise programs, physiotherapy supervised rehabilitation resulted in less pain and subjective instability at 8 wk after ankle sprain (Feger 2015 **Level I,** 1 RCT: van Rijn 2009, **Level II**, n=102, JS 3).

Dysmenorrhoea

Physical activity (single or co-intervention) in any setting or via any mode for the treatment of primary dysmenorrhea (non-athlete females with regular menstruation not using hormonal contraception) reduces pain intensity (MD -1.89/10; 95%CI -2.96 to -1.09) and pain duration (MD -3.92 h; 95%CI -4.86 to -2.97) (Matthewman 2018 **Level I** [PRISMA], 11 RCTs, n=817 [intensity] & n=469 [duration]). Yoga (20 min/day for 14 d/cycle) vs no treatment improved pain intensity from dysmenorrhea at 1 mth (MD -3.2/10; 95%CI -2.2 to -4.2) (Kannan 2014 **Level I**, 1 RCT: Rakhshaee 2011, **Level II**, n=92, JS 1). Overall quality of this evidence was rated as low due to high risk of bias.

Labour pain

The use of birth ball exercises for labour pain relief improves pain (MD -0.9/10; 95% CI -1.3 to -0.6) (Makvandi 2015, **Level I**, 3 RCTs, n=205). Overall, the quality of the studies was mixed, with most providing little information on the exact methods they used**.**

KEY MESSAGES

1. Following total knee arthroplasty, an exercise intervention in addition to standard post-operative interventions for 8 weeks after discharge may reduce pain and improve function (**N**) (**Level I**).
2. In primary dysmenorrhoea, exercise may reduce acute pain intensity and pain duration (**N**) (**Level I**).
3. Use of a birth ball may improve labour pain (**N**) (**Level I**).

The following tick boxes represent conclusions based on clinical experience and expert opinion:

☑ Clear recommendations on the components of exercise interventions (including time point of application, frequency, mode, dose and duration) for acute postoperative pain management cannot be made; different surgical procedures may require different exercise-based interventions (**N**).

☑ Immediate post-operative weight bearing post anterior cruciate ligament reconstruction may reduce pain and does not appear to result in increased joint laxity (**N**).

Total joint arthroplasty

Following TKA, despite improvements in function and quadriceps strength, there was no effect of prehabilitation on postoperative pain pooled across heterogeneous time points and scales nor were significant differences were found at ≤6 wk (3 RCTs) or 3 mth (9 RCTs) (Moyer 2017 **Level I** [PRISMA], 16 RCTs, n=1,178). Multiple systematic reviews and meta-analyses with significant study overlap come to the same conclusion, with no significant effects demonstrated for:

- Pain intensity at 1 mth (2 RCTs, n=297) or WOMAC scores at 3 mth (3 RCTs, n=252) (Cabilan 2016 **Level I**, 5 RCTs, n=549);
- Pain measured variously by WOMAC (5 RCTs), SF-36 (4 RCTs) or VAS (2 RCTs) (Kwok 2015, **Level III-1 SR**, 8 studies, n=619);
- WOMAC pain intensity between 1.5 and 3 mth (Chen 2018 **Level I**, 7 RCTs, n=424);
- Pain at 6 or 12 wk (Tedesco 2017, **Level I** [PRISMA], 3 RCTs, n=110).

For THA, in addition to improving function, prehabilitation reduces postoperative pain scores vs usual care when pooled across heterogeneous time points (SMD 0.15; 95% CI 0.03 to 0.27) (Moyer 2017, **Level I** [PRISMA], 13 RCTs, n=905). When analysed at specific time periods, pain scores are reduced at 3 mth vs usual care (3 RCTs) (SMD 0.34; 95%CI 0.07 to 0.62), but not at ≤6 wk (7 RCTs) or 6 mth (3 RCTs).

When any joint replacement surgery was considered, prehabilitation reduces pain at 4 wk or less (assessed by multiple scales: WOMAC, VAS, Knee injury and Osteoarthritis Outcome Score (KOOS) and 10 graded scale, subsequently converted to WOMAC 0-100 subscales) (WMD -6.1/100; 95%CI -10.6 to -1.6) (Wang 2016 **Level I** [PRISMA]**,** 2 RCTs, n=105 [THA] & 2 RCTs, n=114 [TKA]). The authors noted a low overall quality of evidence in these trials. No significant difference between prehabilitation and usual care groups for pain is seen at 6 to 8 wk (5 RCTs, n=488) or 12 wk (10 RCTs, n=806) post-operation.

Anterior cruciate ligament (ACL) reconstruction

For ACL reconstruction, despite improving function and strength, prehabilitation does not significantly improve patient reported pain vs controls (Alshewaier 2015 **Level I** [PRISMA], 3 RCTS, n=291).

Spinal Surgery

For spinal surgery, in spite of earlier discharge times and reduced time to functional milestones, prehabilitation did not improve pain at one or 3 mth (Cabilan 2016 **Level I**, 1 RCT: Nielsen 2010, **Level II**, n=60, JS 3).

Dosing of prehabilitation

A systematic review looking at prehabilitation duration in TKA, THA and spinal surgery patients shows no effects of quantity on WOMAC pain scores (Cabilan 2015 **Level I** [PRISMA], 2 RCTs [<500 min], 3 RCTs [500-999 min], 2 RCTs [1,000-1,499 min], 2 RCTs [>= 1,500 min]). A single RCT (n=23) in the 1,000 to 1,499 min range reported an improvement in pain intensity (5.5/10 ± 2.2 vs 7.3/10 ± 2.0), but not WOMAC scores.

KEY MESSAGES

1. Prior to total hip arthroplasty, prehabilitation may reduce postoperative hip pain at 3 months (**N**) (**Level I** [PRISMA]).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ A recommendation for the specific type of prehabilitation and dosing parameters cannot be made at this time (**N**).

7.5.1.3 | Rehabilitation

Spinal Surgery and Injuries

After spinal surgery, physiotherapy commenced within the first 4 wk reduces pain at 12 wk (SMD -0.38; 95%CI -0.66 to -0.10) and 12 to 18 mth (SMD -0.30; 95%CI -0.59 to -0.02) vs no or sham physiotherapy (Snowdon 2016 **Level I** [PRISMA], 4 RCTs, n=250). Early comprehensive physiotherapy (active rehabilitation, education on the performance of daily functional tasks, functional weight-bearing exercise, cardiovascular endurance exercise, lower limb strengthening and dynamic proximal stabilisation) does not increase the risk of adverse events (3 RCTs, n=196).

For osteoporotic vertebral compression fractures, spinal orthoses reduce pain (SMD -1.47; 95%CI -1.82 to -1.13) vs no intervention over the medium term (Rzewuska 2015 **Level I**, 2 RCTs, n=170). However, there was no difference in pain between a proprietary spinal orthosis (SpinoMed®) and a soft lumbar orthosis at short-term follow up (Li 2015 **Level II**, n=51, JS 1).

Total knee arthroplasty (TKA)

After TKA, accelerated physiotherapy (starting within 24 h) versus standard physiotherapy (after bed rest for 24 h) reduced time to discharge by 2.1 days (± 1.45) and pain at the time of discharge (MD −0.96/10; 95%CI −1.21 to −0.71) (Henderson 2018, **Level I** [PRISMA], 1 RCT: Labraca 2011, **Level II**, n=273, JS 3). Twice daily vs once daily physiotherapy did not significantly reduce pain (Henderson 2018, **Level I** [PRISMA], 1 RCT: Lenssen 2006 **Level II**, n=43, JS 3).

After TKA, continuous passive motion (CPM) does not improve pain vs standard care over the short term (< 6 wk) (Tedesco 2017 **Level I** [PRISMA], 9 RCTs, n=1,025; Harvey 2014, **Level I** [Cochrane], 8 RCTs, n=414) (7 RCTs overlap). No difference was found for adverse events.

Anterior cruciate ligament (ACL) reconstruction

After outpatient ACL reconstruction, the role of mobilisation strategies was investigated (Secrist 2016 **Level I** [PRISMA], 3 RCTs, n unspecified). Individual trials showed that CPM use for 16 h/d immediately after surgery did not decrease pain vs controls, but did decrease PCA usage (41 mg ± 18.9 vs 65 mg ± 21.4) (Secrist 2016 **Level I** [PRISMA], 1 RCT: McCarthy 1993 **Level II**, n=35, JS 1). A continuous active motion device, in which the patient used the contralateral leg to pedal the injured leg, did not decrease VAS scores vs a CPM device (Secrist 2016 **Level I** [PRISMA], 1 RCT: Friemert 2006 **Level II**, n=60, JS 1). There was no difference in pain between an unhinged immobilising brace for 2 wk postoperatively and no immobilisation (Secrist 2016 **Level I** [PRISMA], 1 RCT: Hiemstra 2009 **Level II**, n=82, JS 2).

Movement representation

Movement representation (mirror therapy, motor imagery, action observation combined with standard physiotherapy or rehabilitation) techniques reduced limb pain acutely

(SMD -0.7; 95%CI -1.24 to -0.15) (Thieme 2016, **Level I** [PRISMA], 6 RCTs, n=140). A sub-analysis of both acute and chronic pain by type found reductions in pain for Complex Regional Pain Syndrome (CRPS) (SMD -2.23; 95%CI -3.88 to -0.57) (4 RCTs, n=108) and nociceptive pain conditions (ankle sprain, ACL reconstruction, TKA and rotator cuff injury) (SMD -1.26; 95%CI -1.92 to -0.61) (4 RCTs, n=64), but not phantom limb pain (3 RCTs, n=41) or post stroke pain (3 RCTs, n=116).

See also Section 8.1.5.2.

KEY MESSAGES

1. Early comprehensive active physiotherapy in the first 4 weeks post spinal surgery may reduce pain and does not appear to increase adverse events (**N**) (**Level I** [PRISMA]).
2. Movement representation interventions (mirror therapy/motor imagery) may reduce acute pain after trauma and surgery (**N**) (**Level I** [PRISMA]).

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ Accelerated rehabilitation, started within 24 hours post total knee arthroplasty, may reduce pain at the time of discharge (**N**).

7.5.2 | Manual and massage therapies

Postoperative pain in general

Massage improves postoperative pain vs routine care (SMD -0.58; 95%CI -0.93 to -0.53) (Kukimoto 2017, **Level I** [PRISMA], 9 RCTs, n=1,105). Reductions in pain are seen in both single dose (SMD -0.49; 95%CI -0.64 to -0.34) (6 RCTs, n=757) and multiple doses of massage (SMD -0.53; 95%CI -0.91 to -0.14) (7 RCTs, n=1,031). When analysed for incision type, the beneficial effects of massage on postsurgical pain persists for both sternal (SMD -0.68; 95%CI -0.91 to -0.46) (4 RCTs, n=333) and abdominal incisions (SMD -0.57; 95%CI -1.04 to -0.11) (2 RCTs, n=193).

Cardiac and thoracic surgery

In addition to reducing anxiety, massage reduces pain intensity after cardiac surgery (MD −1.52/10; 95%CI −2.2 to −0.84) (Miozzo 2016 **Level I** [PRISMA], 10 RCTs, n=409). Different forms of massage have also been found to have significant beneficial effects on pain post cardiac surgery: Integrative massage (n=113 [2 sessions]), Swedish massage (n=152 [2 sessions]), Thai massage (n=74 [one session]) and general massage (n=40 [3 sessions]; n=65 [one session]) (Ramesh 2015**, Level I** [PRISMA], 7 RCTS, n=764). One included RCT showed no effect for general massage (n=252 [2 sessions]).

20 to 30 min of healing coach (health care professionals with special training in massage or touch therapy or massage therapist-administered massage) added to standard analgesia reduces pain vs standard care alone (MD -0.85/10; 95%CI -1.28 to -0.42) (Boitor 2017 **Level I** [PRISMA], 7 RCTs, n=1,087); similar results are found in the early period after ICU discharge (MD -0.89/10; 95%CI -1.45 to -0.33) (6 RCTs, n=684). Additionally, 10 to 20 min of massage in conjunction with analgesia administered by a nurse or massage therapist significantly reduces pain in ICU (MD -0.80/10; 95%CI -1.25 to -0.35) (3 RCTs, n=462), while massage without analgesia also reduces pain (MD-2.47/10; 95%CI -4.88 to -0.06) (2 RCTs, n=150).

Labour

Massage reduces pain intensity in first stage labour vs standard care (SMD −0.81; 95%CI −1.06 to −0.56) (6 RCTs, n=362), but not at the second (SMD −0.98; 95%CI −2.23 to 0.26) (2 RCTs, n=124) or third stage (SMD −1.03/10; 95%CI −2.17 to 0.11) (2 RCTs, n=122) vs standard care (Smith 2018, **Level I** [Cochrane], 6 RCTs, n=362). Massage vs a music intervention reduced severe labour pain (RR 0.40; 95% CI 0.18 to 0.89) (1 RCT, n=101).

An earlier systematic review (including only studies from Iran) found that in labour, massage reduces labour pain across all phases including: latent (SMD −1.23; 95%CI −1.73 to −0.74) (9 RCTs, n=642), active (SMD −1.59; 95%CI −2.06 to −1.12) (7 RCTs, n=422) and transitional (SMD −1.90; 95%CI −3.09 to −0.71) (6 RCTs, n=362) as well as having an overall effect (SMD −1.52; 95%CI −1.90 to −1.14) (Ranjbaran 2017 **Level I** [PRISMA], 10 RCTs, n=702) (1 RCT overlap).

Primary dysmenorrhea

In primary dysmenorrhea, manipulative therapy may reduce pain vs sham (WMD -0.94/10; 95%CI -0.66 to -1.2) (Abaraogu 2017 **Level I**, 3 RCTs, n=217); however, these studies were methodologically heterogeneous.

Acute back pain

Manual therapy is also considered with respect to Acute Back Pain in the NICE guidelines NICE 2018 and the older Australian Acute Musculoskeletal Pain Guidelines (Australian Acute Musculoskeletal Pain Guidelines Group 2003 **GL**). See also Section 8.7. and 8.8.

KEY MESSAGES

1. Single and multiple doses of massage in the early postoperative period may reduce pain after surgical procedures, including cardiac surgery (**N**) (**Level I [**PRISMA])
2. Massage may decrease pain in the first stage of labour pain compared to standard care (**N**) (**Level I** [Cochrane Review])

The following tick box represents conclusions based on clinical experience and expert opinion:

☑ The role of manipulative therapy in primary dysmenorrhea is currently unclear (**N**).

7.5.3 | Warming and cooling interventions

7.5.3.1 | Warming interventions

Dysmenorrhea

In a 4-arm RCT, treatment with heat pads reduced pain vs placebo (unheated pads) (MD 1.8/10; 95%CI 0.9 to 2.7), but ibuprofen plus heat pad was no more effective than ibuprofen with placebo heat pad (Kannan 2014 **Level I** 1 RCT: Akin 2001, **Level II**, n=81, JS 3). Time to noticeable pain relief was reduced from 2.8 h to 1.5 h with ibuprofen plus heat pad vs ibuprofen with placebo heat pad.

A subsequent review identified three further studies. Heat therapy interventions including heat patches (1 study, n=147), hot water (1 study, n=44) and heated red bean pillows (1 study, n=51), improves pain from dysmenorrhoea, however high heterogeneity and a lack of placebo controls prevent firm conclusions (Igwea 2016 **Level III-1 SR**, 3 studies, n=242).

Labour pain

Warm packs vs usual care reduce pain intensity in the first stage of labour (SMD −0.59; 95%CI −1.18 to −0.00) (3 RCTs, n=191) and second stage of labour (SMD -1.49; 95%CI −2.85 to −0.13) (2 RCTs, n=128) (Smith 2018 **Level I** [Cochrane], 14 RCTs, n=1,172). Thermal manual methods resulted in a reduction in pain intensity vs usual care (MD −1.44/10; 95%CI −2.24 to −0.65) (1 RCT, n=96) and intermittent hot and cold packs reduced pain in the first phase of labour vs usual care (MD −1.46/10; 95% CI −2.59 to −0.33) (1 RCT, n=48).

Periocular surgery

Warming the local anaesthetic agent so it is close to body temperature when injected decreased pain in one of two small RCTs (Gostimir 2019, **Level I** [PRISMA], 2 RCTs, n=100).

7.5.3.2 | Cooling interventions

All knee surgery

Compression cryotherapy vs cryotherapy alone after any knee surgery improves pain on POD 1 (MD -0.94/10; 95%CI -1.63 to -0.26) (7 RCTs, n=420), POD 2 (MD -0.55/10; 95%CI -0.78 to -0.32) (7 RCTs, n=420) and POD 3 (MD -0.46/10; 95%CI -0.87 to -0.05) (2 RCTs, n=100) (Song 2016 **Level I** [PRISMA], 10 RCTs [2 TKA, 3 arthroscopy, 5 ACL reconstruction], n=662).

Knee Arthroplasty

Cryotherapies reduces pain after TKA (MD -0.51/10; 95%CI -1.00 to -0.02) (8 RCTs, n=1,382) (Tedesco 2017 **Level I** [PRISMA], 12 RCTs [cryotherapy], n=1,382; Ni 2015 **Level I**, 13 RCTs [9 TKA, 2 THA, 1 mixed], n=782) (9 RCT overlap). However, when data for POD 1 (7 RCTs, n=529), POD 2 (5 RCTs, n=422) and POD 3 were considered separately, no effect is seen. Cryotherapy is also not better than compression therapy (5 RCTs, n=407).

Anterior cruciate ligament (ACL) reconstruction

Cold compress devices improve pain 48 h after ACL surgery vs no therapy (MD -1.41/10; 95%CI -1.66 to -1.17) (2 studies, n=71) (Martimbianco 2014 **Level III-1 SR** [PRISMA], 10 studies, n=573) (2 RCTs overlap with Song 2016). There is no effect from cold therapy (3 studies) or cold compression therapy with cold water vs room temperature water (placebo) (3 studies). Cold compression therapy vs ice packs reduces pain at 1 wk (1 RCT, n=44) and 6 wk (1 RCT, n=36). Cold compression devices vs ice packs or no cold therapy reduce the amount of medication taken by patients (6 studies).

A subsequent systematic review of cryotherapy following outpatient ACL surgery shows superior pain relief in 4 of 8 studies vs no cryotherapy or water at room temperature (Secrist 2016, **Level III-1 SR** [PRISMA]**,** 10 studies, n unspecified) (8 studies overlap with Martimbianco 2014).

Haemarthrosis of haemophilia

Cryotherapy has been recommended for treatment of pain and swelling in haemarthrosis due to haemophilia (Rodriguez-Merchan 2018 **NR**).

Venipuncture

Vapocoolants for pain during IV cannulation vs pooled no or placebo treatments reduce pain when assessed as a continuous measure (SMD -0.53; 95%CI -0.83 to -0.23) (8 RCTs, n=682) or dichotomised (OR 4.62; 95%CI 1.84 to 11.63) (4 RCTs, n=681) (Zhu 2018 **Level I**, 11 RCTs, n=1,410). However, in the paediatric subgroup analysis (2 RCTs, n=172), no effect is seen. A prior meta-analysis also concluded that vapocoolants are superior to pooled no or placebo treatment; however, with increased discomfort at the time of application (Griffith 2016 **Level I** [Cochrane], 9 RCTs, n=1,070) (8 RCTs overlap). In contrast, an earlier systematic review including non-RCTs

does not confirm all these findings (Hogan 2014 **Level III-I SR** [PRISMA]**,** 12 studies, n unspecified) (8 RCTs overlap).

See also Section 10.7.2 for paediatric specific information.

Periocular Surgery

Application of ice for 2 min before injection of local anaesthesia reduced pain (Gostimir 2019 **Level I** 1 RCT**:** Goel 2006 **Level II**, n=39, JS 2). In a crossover trial, patients received two injections, one where treatment with ice (for 2 min) occurred prior to unbuffered lidocaine injection vs another where buffered lidocaine was injected without ice pretreatment; with less pain at the site of the ice-treated unbuffered injection (Huang 2015 **Level III-2**, n=60).

Tonsillectomy

Cryotherapy (ice lollipop) over 4 h reduced pain post-tonsillectomy in children (2 to 12 y) at 30 min and 1 h (Keefe 2018 **Level I** [PRISMA] 1 RCT**:** Sylvester 2011 **Level II**, n=87, JS 3). Intraoperative cryotherapy with a cryotherapy probe (-56°C) (1 RCT) and ice-water cooling (4°C to 10°C) (2 RCTs) reduces post-tonsillectomy pain scores consistently vs no treatment by 21 to 32% (0.9/10 to 1.8/10) (Raggio 2018 **Level I** [PRISMA], 3 RCTs, n=153).

Dental Surgery

After 3rd molar extraction, cryotherapy is effective at reducing oedema, but mixed results were found with regard to effect on pain where 5 of 11 studies were positive (Fernandes 2019 **Level IV SR**, 11 studies, n=721).

Maxillofacial surgery

Hilotherapy (the application of cold compression at a regulated temperature through a face mask) reduces pain on POD 2 after facial skeletal surgery vs cold compression (MD -2.37/10; 95%CI -3.24 to -1.50) (n=146) and reduces swelling on POD 2 and POD 3, but not POD 28 (Glass 2016 **Level I** [PRISMA], 6 RCTs, n=286).

Mucositis

Cryotherapy during chemotherapy may have a preventive effect on mucositis see Section 8.9.8.2.

Labour

Cold packs reduce pain intensity in the first stage of labour (MD −1.43/10; 95%CI −2.56 to −0.30) (Smith 2018 **Level I** [Cochrane] 1 RCT: Shirvani 2014 **Level II**, n=64, JS 3).

Puerperium perineal pain

There is only limited evidence to support the effectiveness of local cooling treatments (ice packs, cold gel pads, cold/iced baths) for relieving perineal trauma pain vs various alternatives or no interventions (East 2012 **Level I** [Cochrane], 10 RCTs, n=1,825). Ice packs provided superior analgesia vs no treatment for 24 to 72 h postpartum (RR 0.61; 95%CI 0.41 to 0.91) (1 RCT, n=208).

KEY MESSAGES

1. Heat packs may reduce labour pain during the first and second stages (**N**) (**Level I** [Cochrane Review]).
2. Vapocoolants may reduce the pain of intravenous cannulation in adults but its application is associated with discomfort (**N**) (**Level I** [Cochrane Review]).
3. Cryotherapy may reduce pain after total knee arthroplasty but is not superior to compression (**N**) (**Level I** [PRISMA]).
4. Compression cryotherapy may reduce acute pain and analgesia requirements post anterior cruciate ligament reconstruction and pain on day one to three post knee surgery (**N**) (**Level I** [PRISMA]).
5. Intraoperative cryotherapy may reduce post-tonsillectomy pain (**N**) (**Level I** [PRISMA]).
6. Hilotherapy (the application of cold compression at a regulated temperature through a face mask) may reduce pain and swelling after facial skeletal surgery vs cold compression (**N**) (**Level I** [PRISMA]).
